ABSTRACT: ENSO episodes affect South American precipitation and the frequency of extreme precipitation events, mainly in the La Plata Basin (LPB). We analyzed the representation of Central and Eastern ENSO diversity in a historical simulation of the HadGEM2-ES model, and the results showed that this model does not reflect the ENSO diversity. However, the model does represent the frequency of Eastern ENSO. Therefore, we used this model to analyze the influences of this type of ENSO on precipitation and frequency of extreme precipitation events over the LPB in simulations (historical scenario) and projections (RCP8.5 scenario), during austral summer and autumn. The HadGEM2-ES model reproduced the anomalous precipitation dipole pattern (increased precipitation over southeastern South America and decreased precipitation over the north/northeast) in eastern El Niño during both seasons, and the opposite pattern in eastern La Niña during the austral autumn. The model reproduced the patterns of anomalous frequency of extreme events that occur over South America during both seasons of eastern El Niño, but failed to reproduce these patterns during eastern La Niña. The future projections showed patterns of anomalous precipitation and frequency of extreme events that were similar to those simulated for the present, but were more intense and affected a wider area.

1. INTRODUCTION

Recent studies have shown the importance of studying the influence of different types of El Niño–Southern Oscillation (ENSO) events separately (Ashok et al. 2007, Kao & Yu 2009, Kug et al. 2009, Yeh et al. 2009, Tedeschi et al. 2013, 2015). The main sea surface temperature (SST) anomalies (SSTA) in ENSO episodes occur in the eastern equatorial Pacific or central equatorial Pacific. These different types of ENSO influence the South American precipitation in different ways. During austral summer (December–January–February, DJF) the eastern Pacific El Niño (EEN) induces precipitation increases over southeastern South America and decreases over

northern/northeastern South America, while during central Pacific El Niño (CEN), precipitation decreases over southeastern, central-eastern, and central-northern South America (Li et al. 2011, Tedeschi et al. 2013, 2015). In austral autumn (March–April–May, MAM), EEN produces the same DJF patterns of dry conditions in the north and wet in the south, while CEN induces increased precipitation over central-eastern South America (Tedeschi et al. 2013). The precipitation anomaly patterns over South America during MAM of La Niña years are similar during the 2 types of ENSO, but normally, the patterns during La Niña in the central Pacific (CLN) are stronger than La Niña in the eastern Pacific (ELN) (Tedeschi et al. 2013, 2015).

The frequency of central Pacific ENSO has increased in recent decades (Yeh et al. 2009, Lee & McPhaden 2010, Na et al. 2011, Yu & Kim 2013). Thus, it is important to know whether models can simulate the influence of different types of ENSO on global atmospheric variables, to analyze future climate projections.

The Earth System models are the most advanced tools to represent the physical processes that occur in the climate system (atmosphere, ocean, cryosphere, biosphere, and atmospheric chemistry) and the interaction among them (IPCC 2013). Taschetto et al. (2014) used 34 coupled models of Coupled Model Intercomparison Project Phase 5 (CMIP5) to assess the representation of ENSO during the historical period and in future climate projection scenarios. Results of these models were assessed in the fifth report of the IPCC (IPCC-AR5, IPCC 2013). The majority of models can reproduce the intensity and location of maximum SSTA during ENSO. Moreover, they can represent the magnitude of the asymmetry between El Niño and La Niña and the differences between 2 types of El Niño, but fail to represent the differences between the 2 types of La Niña (Taschetto et al. 2014). Steinhoff et al. (2015) showed that CMIP5 models can represent the sign of precipitation anomalies over Central America and northwestern South America during the ENSO that occurs in the eastern Pacific, and Tedeschi & Collins (2016) showed the same results for tropical South America when they analyzed different types of ENSO, but both studies indicated that CMIP5 models have problems in simulating the magnitude of precipitation anomalies. Furthermore, Tedeschi & Collins (2016) reported that CMIP5 models have difficulty in simulating the correct sign of precipitation anomalies during different types of ENSO in central and southeastern South America.

Cavalcanti & Shimizu (2012) showed that the HadGEM2-ES model can simulate well the seasonal variability of precipitation, temperature, and winds over South America in the historical period (1979/1980–2004/2005), especially the difference between the austral winter (June–July–August, JJA) and summer (DJF). Furthermore, the model can also represent one of the main features of DJF precipitation variability, viz. the South Atlantic Convergence Zone and the Pacific–South America teleconnection.

The main objective of the present study was to evaluate the ability of HadGEM2-ES to represent the influence of ENSO on precipitation and extreme precipitation events over the La Plata Basin (LPB;

38–14° S, 6–43° W) during historical simulations and future projections. In addition, the model's ability to represent 2 types of ENSO is discussed.

2. DATA AND METHODS

2.1. Data

The period of observed data and the model historical simulation is 1960–2005, and the period of future model projections is 2054–2099. The historical simulations of CMIP5 end in 2005. The observed monthly SST dataset was obtained from the Extended Reconstructed Sea Surface Temperature database (NOAA_ERSST_V3, Smith et al. 2008), with a resolution of 1° latitude × 1° longitude. The monthly atmospheric data (horizontal wind components and specific humidity) with a grid resolution of 2.5° × 2.5° were obtained from NCEP/NCAR reanalysis (Kalnay et al. 1996). The vertically integrated moisture flux was calculated from 1000 to 100 hPa. The daily observed precipitation from 2 different datasets (daily precipitation from stations and data of Liebmann & Allured 2005) were interpolated in a grid with a resolution of 1° × 1°. The data of Liebmann & Allured (2005) were only used in grid boxes where we did not have station data, and the interpolation was made by averaging the station data within circles with a radius of 0.707°, whose centers were separated by 1.0°. Monthly precipitation datasets were calculated from the monthly average of daily data.

The HadGEM2-ES is the Hadley Centre global earth system model and is part of the CMIP5 project. This model has a good representation of the atmospheric patterns and precipitation over South America, mainly the Amazon region (Cavalcanti & Shimizu 2012). In the present study, 4 members of the HadGEM2-ES historical run (1960–2005) were used to evaluate the model's ability to represent 2 types of ENSO and the influence of eastern ENSO on South America, mainly on the LPB. Four members of the RCP8.5 scenario (2054–2099) were analyzed to verify how a climate change scenario affects this influence. The atmospheric component of the HadGEM2-ES has a grid with 192 points in latitude and 144 points in longitude (1.25° × 1.875°), while the oceanic component has a grid with 360 × 216 points (1° × 1°, except between the poles and 30°, where the resolution increases smoothly until 1/3° near the equator; Collins et al. 2011). The variables from the model are the same from observations, mentioned above.

2.2. Methodology

2.2.1. ENSO years

The methodology used to determine the ENSO years was described by Tedeschi et al. (2015), and Fig. 1 shows the regions to define the type of ENSO. Positive SSTA (i.e. $>0.5^{\circ}\text{C}$) in the East Pacific region (5°N – 5°S , 140° – 90°W), during at least 6 consecutive months, including October, November, and December of the beginning year of the event (year 0) and January of the following year (year +) (based on Trenberth 1997), characterizes an EEN, and negative SSTA (i.e. $<-0.5^{\circ}\text{C}$) in the same region characterizes an ELN. When these anomalies occur in the Central Pacific region (5°N – 5°S , 160°E – 150°W), CEN or CLN is identified. If 1 year belongs to the 2 categories, the annual SSTA average is calculated in each region, and the episode is assigned to the category corresponding to the highest value. We consider that an ENSO year starts in September (year 0) and finishes in August (year +); therefore, the seasons during the ENSO years are: September–October–November in the beginning year [SON(0)], December in the beginning year and January–February in the following year [D(0)JF(+)], March–April–May in the following year [MAM(+)] and June–July–August in the following year [JJA(+)]. In the present study, only D(0)JF(+) and MAM(+) are analyzed.

Tedeschi et al. (2015, their Table I) showed the years when the ENSO phenomena begin in ERSST-v3 data. The same method was applied for all members of HadGEM2-ES (historical and RCP8.5 scenarios).

2.2.2. Composites of oceanic and atmospheric fields during ENSO

Composites of D(0)JA(+) and MAM(+) anomaly fields (SST, precipitation, horizontal wind at 200 hPa, and vertically integrated moisture flux) were calculated for Eastern ENSO. The statistical significance of the composites was obtained using the test based on

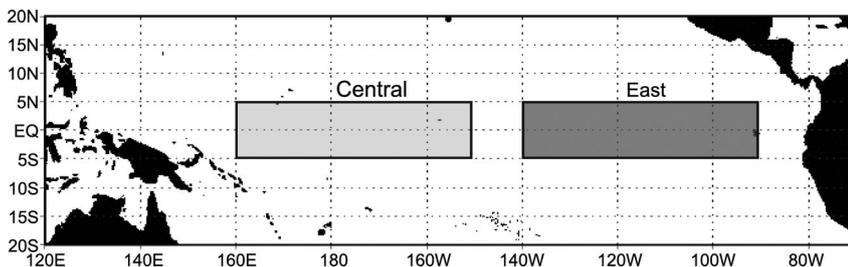

Fig. 1. Areas of Central and Eastern ENSO

Table 1. Number of years in each ENSO category. ERSST-v3 is a dataset developed by NOAA, and is described in Smith et al (2008). The historical and RCP8.5 HadGEM2-ES runs have 4 members each. The ensemble-mean number of ENSO episodes is given in parentheses. CEN (EEN): central (eastern) El Niño; CLN (ELN): central (eastern) La Niña

	CEN	EEN	CLN	ELN	Neutral
ERSST-v3	6	8	8	7	17
HadGEM2-ES, historical	8 (2)	36 (9)	7 (1.75)	34 (8.5)	99 (24.75)
HadGEM2-ES, RCP8.5	2 (0.5)	36 (9)	3 (0.75)	26 (6.5)	117 (29.25)

a hypergeometric distribution (Meyer 1970, Grimm et al. 1998, 2000, Grimm & Tedeschi 2009, Tedeschi et al. 2013, 2015). The number of years in each ENSO category is presented in Table 1. The frequency of Central ENSO in the HadGEM2-ES ensemble is very low, compared to the observation. Therefore, the occurrence of few Central ENSO cases does not allow us to analyze the differences in atmospheric composites between Central and Eastern ENSO. SSTA composites were calculated for Central and Eastern ENSO, while the other atmospheric composites were calculated only for Eastern ENSO.

The CMIP5 scenario shows trends in atmospheric and oceanic data in future scenarios. Therefore, the trends were removed (using linear trends calculated between 2054 and 2099) in all grid points, for all atmospheric and oceanic data of future projections (RCP8.5 scenario), in order to avoid El Niño (La Niña) events being more concentrated at the end (beginning) of the period.

2.2.3. Extreme precipitation events

The methodology used to calculate extreme events of precipitation was defined by Grimm & Tedeschi (2009). This methodology uses the 90th percentile in a Gamma distribution as a threshold to define extreme precipitation events. After calculating the frequency of extreme precipitation events in each season and year in each category (EEN, ELN, and neutral, i.e. years that are not classified as ENSO years), the difference between each category of ENSO and the neutral category was calculated. The same hypergeometric distribution test mentioned above was applied to indicate the significance of the results.

3. IMPACTS OF CENTRAL AND EASTERN ENSO ON SEASONAL FIELDS

3.1. Frequency of events

Table 1 presents the total number of episodes in each category, from ERSST-v3 data and the total and ensemble number of the historical and RCP8.5 projection runs. This table shows that the HadGEM2-ES model does not represent well the variability of different types of ENSO during the historical period. While the observed data include 6 (8) CEN (CLN) events, HadGEM2-ES shows only 2 (1.75) CEN (CLN), on average, during the same period. However, this model can represent the frequency of Eastern ENSO (9 [8.5] EEN [ELN], comparable to observed data of 8 [7] EEN [ELN]). Therefore, it can be used to study features over South America represented during Eastern ENSO.

Consistent with the tendency of several models to simulate only 1 type of ENSO (Ham & Kug 2012, Kug et al. 2012, Xu et al. 2014), HadGEM-ES has the same tendency. Previous studies have shown that the frequency and persistence of Central ENSO have increased in recent years (Yeh et al. 2009, Lee & McPhaden 2010, Yu & Kim 2013). CMIP3 model projections for the future indicate that Central ENSO will be more frequent than Eastern ENSO (Yeh et al. 2009). However, in the present study, the HadGEM2-ES model shows different results, as summarized in Table 1. The numbers of Central ENSO (El Niño or La Niña) are lower than Eastern ENSO, both in the present climate and future projections.

3.2. SSTA fields in El Niño and La Niña

3.2.1. EEN and CEN

Fig. 2 shows the SSTA composites of El Niño years. In EEN composites, the simulated patterns (Fig. 2b,e) are similar to the observed patterns (Fig. 2a,d), i.e. strong positive anomalies in the eastern Pacific and negative anomalies in the north and south Pacific (this pattern is known as the boomerang or horseshoe pattern). The projected patterns (Fig. 2c,f) are similar to the historical ones, but with weaker intensity inside the anomalous area.

The simulated SSTA composites of CEN (Fig. 2h,j) show positive SSTA in the central Pacific, consistent with ENSO-year definitions and observed patterns (Fig. 2g,i). During MAM(+), negative SSTA occur in the eastern Pacific near the South American coast, in

the simulated and in the observed data, similar to El Niño Modoki (Ashok et al. 2007, Weng et al. 2007, Tedeschi et al. 2013). However, if the whole globe is analyzed, the simulated and observed patterns are very similar in EEN, while in CEN there are some differences, mainly in the North Pacific and Indian Ocean. These could be linked with the difficulty of the HadGEM2-ES in representing Central ENSO years, coherent with Table 1.

3.2.2. ELN and CLN

The ELN composites show the strongest negative SSTA in the eastern Pacific, in both seasons for the observed dataset and model results (Fig. 3a–f). The strongest anomalies in the eastern Pacific occur in D(0)JF(+) in the observed data, as well as in simulations and projection patterns.

During D(0)JF(+), the simulated patterns of SSTA in CLN reproduce the negative SSTA in the tropical Pacific and positive SSTA in the north and south Pacific. During MAM(+), negative SSTA occur in the central Pacific, around the equator, but there are more differences compared to the observation. In both seasons, the simulated cold anomalies are extended westward with respect to the observed ones. As during CEN, the model does not represent the CLN pattern well, and this also explains its difficulty in identifying different types of ENSO.

3.3. Anomalous precipitation over South America – impacts over LPB

3.3.1. EEN

Several studies have shown that precipitation over southeastern South America, including the LPB, increases during EEN (Ropelewski & Halpert 1987, Aceituno 1988, Grimm et al. 1998, 2000, Grimm 2003, 2004). Observed, simulated, and projected patterns are shown in Fig. 4 during D(0)JF(+) and MAM(+), where it is seen that the observed patterns agree with previous studies. The model reproduces the positive anomalies over LPB in EEN, but they are weaker and shifted southward when compared with observations in the 2 seasons. For example, there is a positive anomaly over Uruguay during EEN in the historical simulation during both seasons that does not occur in the observations. The model also reproduces the negative anomalies in northern South America, but the model fails in simulating the pattern

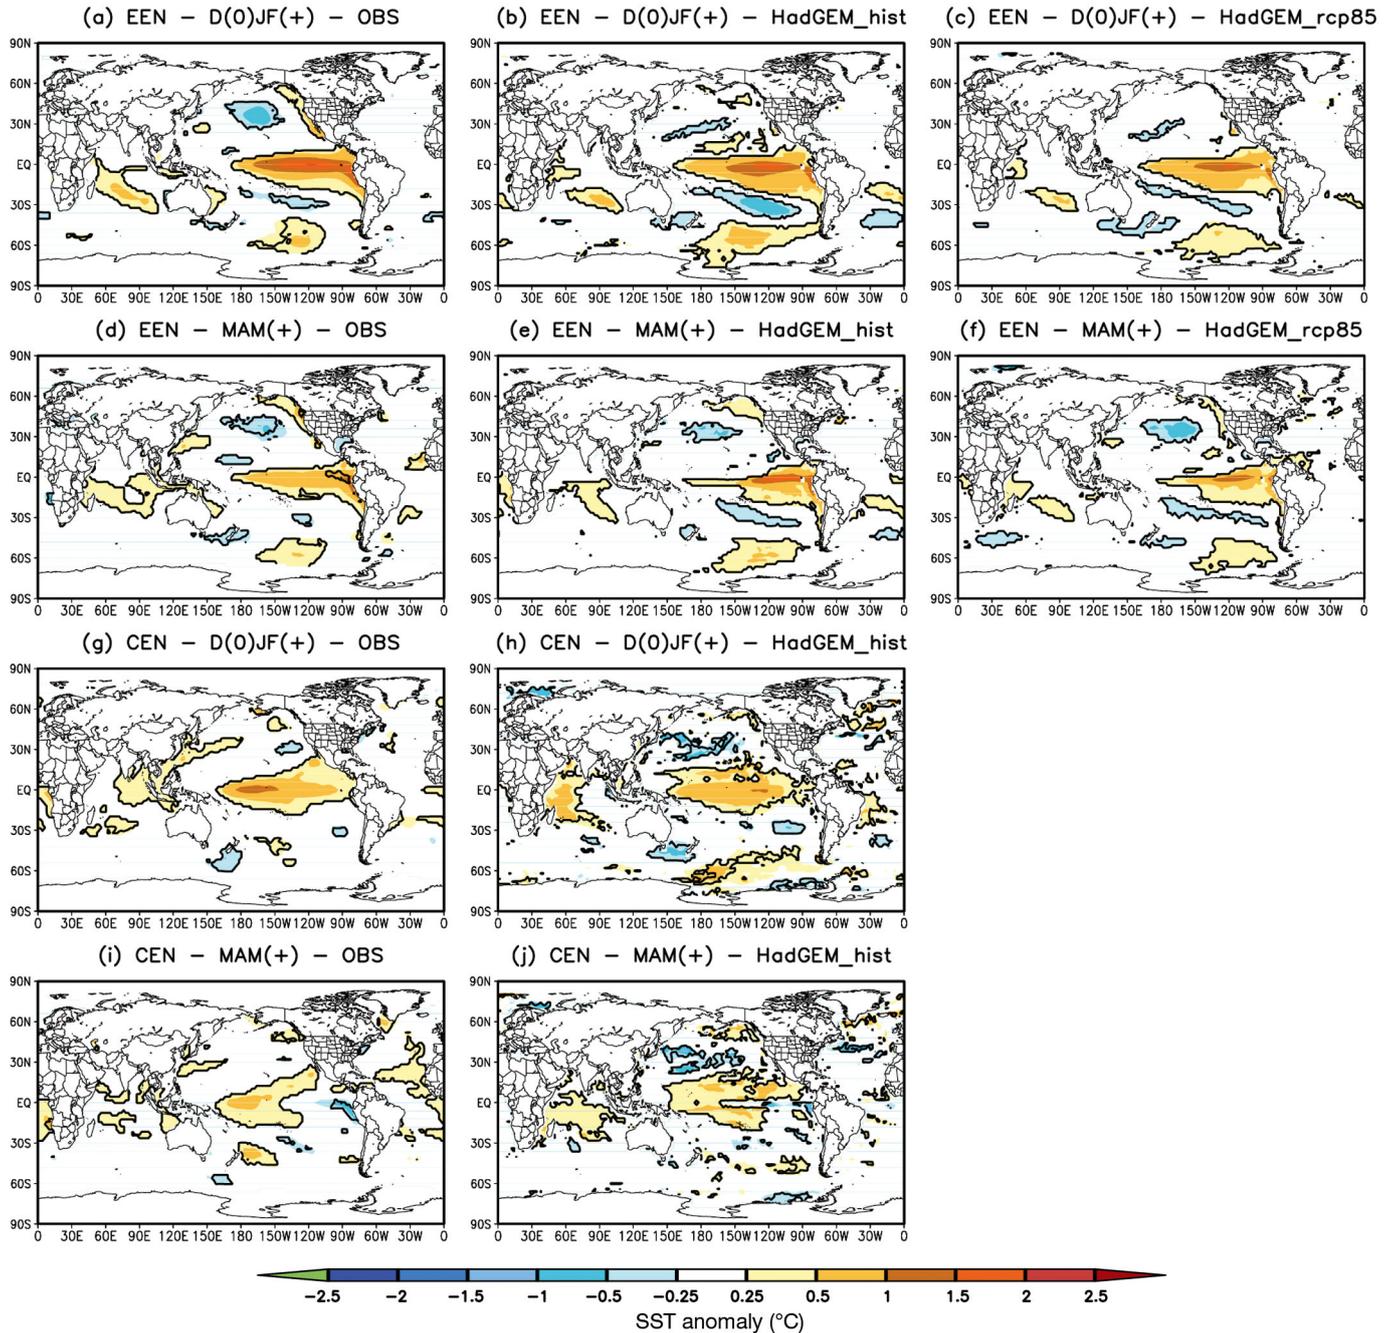

Fig. 2. Composites of SST anomalies during eastern El Niño (EEN) [D(0)JF(+)] (a–c) and MAM(+)] (d–f)] and central EN (CEN) [D(0)JF(+)] (g,h) and MAM(+)] (i,j)] based on observed data (left column), HadGEM2-ES in the historical period (center column), and HadGEM2-ES in the RCP8.5 scenario (right column). Regions with positive (negative) anomalies higher (lower) than 0.25 (–0.25)°C and with a level of confidence >90 % are outlined with a thick black line

in northeastern South America during MAM(+). The future projections indicate increased precipitation over LPB during EEN events, with an even greater reduction of rainfall in the northern/northeastern parts of the continent, especially in summer (Fig. 4b,c). This is consistent with the finding of Grimm & Natori (2006) that in the future climate, the ENSO-

related precipitation mode over South America in spring and in summer shows enhancement of the factor loadings in the northern/northeastern parts of the continent compared to the southeastern region.

The composites of observed and simulated streamline anomalies at 200 hPa during EEN (Fig. 5) are consistent with the precipitation anomalies. The model

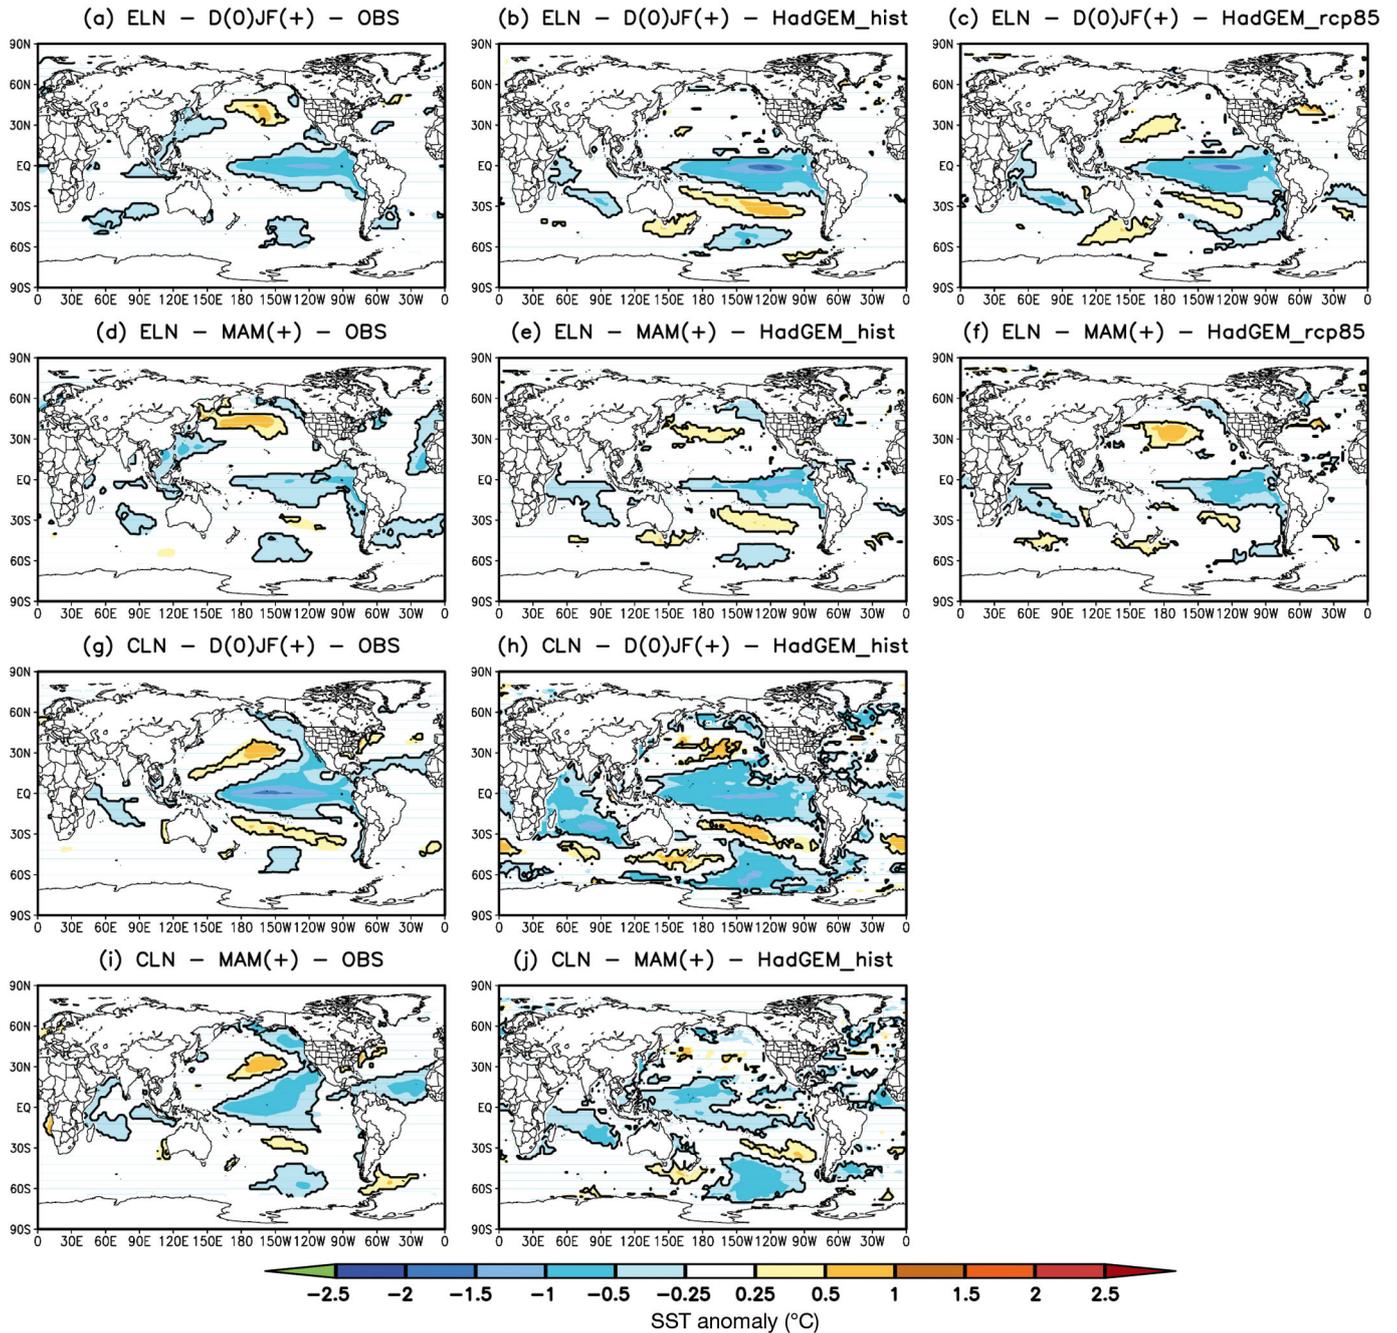

Fig. 3. Same as Fig. 2, but for La Niña years. ELN, CLN: eastern and central La Niña, respectively

represents the 2 anticyclones around the Pacific equatorial region, typical of ENSO, and the wave train tropics–extratropics that favors a pair of cyclonic–anticyclonic circulation over the southwest and southeast coasts of South America. The position of these centers and the strengthening of the subtropical jet cause an increase in precipitation over LPB (Fig. 4). In MAM, the model shows the Northern Hemisphere anticyclonic center around the equator displaced

eastward, and a reduction of the Southern Hemisphere anticyclonic center (approx. 15°S, 120°W) in that region. Notwithstanding, the cyclonic–anticyclonic pair over southeast South America is still present and more organized in both the model and the observation, consistent with the precipitation anomalies. The projections during EEN show similar atmospheric circulation patterns favorable to precipitation anomalies, and the higher rainfall anomaly than in the his-

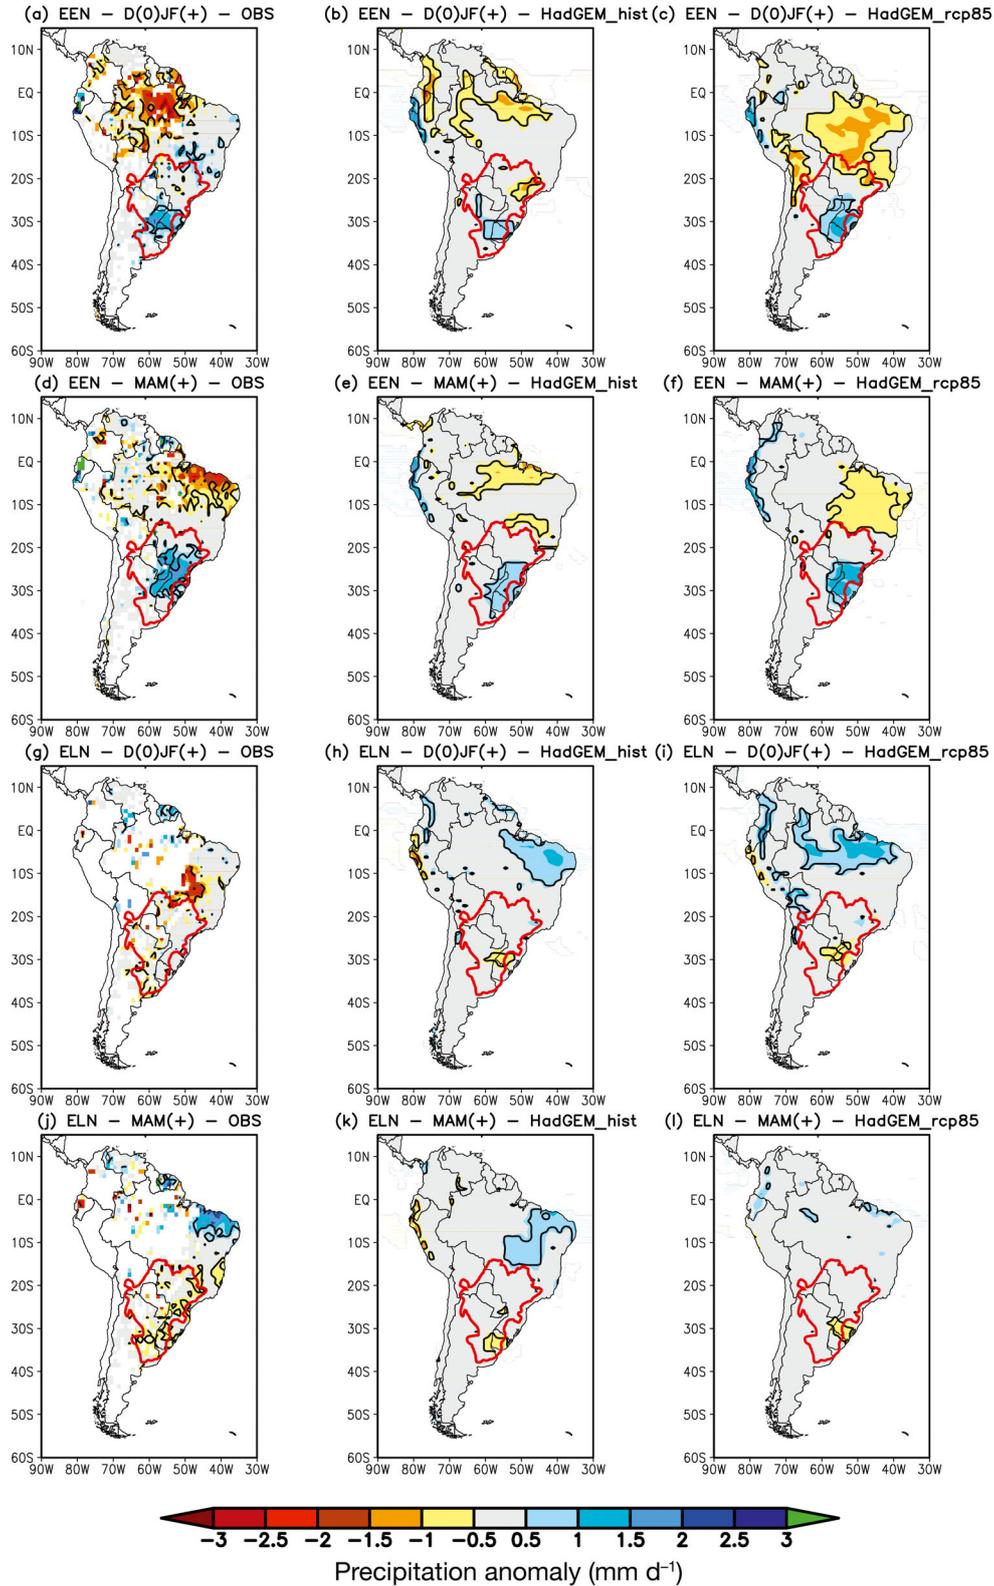

Fig. 4. Composites of precipitation anomalies (mm d⁻¹) during eastern El Niño (EEN) [D(0)JF(+)] (a–c) and MAM(+) (d–f)] and eastern La Niña (ELN) [D(0)JF(+)] (g–i) and MAM(+) (j–l)] based on observed data (left column), HadGEM2-ES in the historical period (center column), and HadGEM2-ES in the RCP8.5 scenario (right column). Regions with positive (negative) anomalies higher (lower) than 0.5 (–0.5) mm d⁻¹ and with a level of confidence >90% are outlined with a thick black line. The position of the La Plata Basin is outlined in red

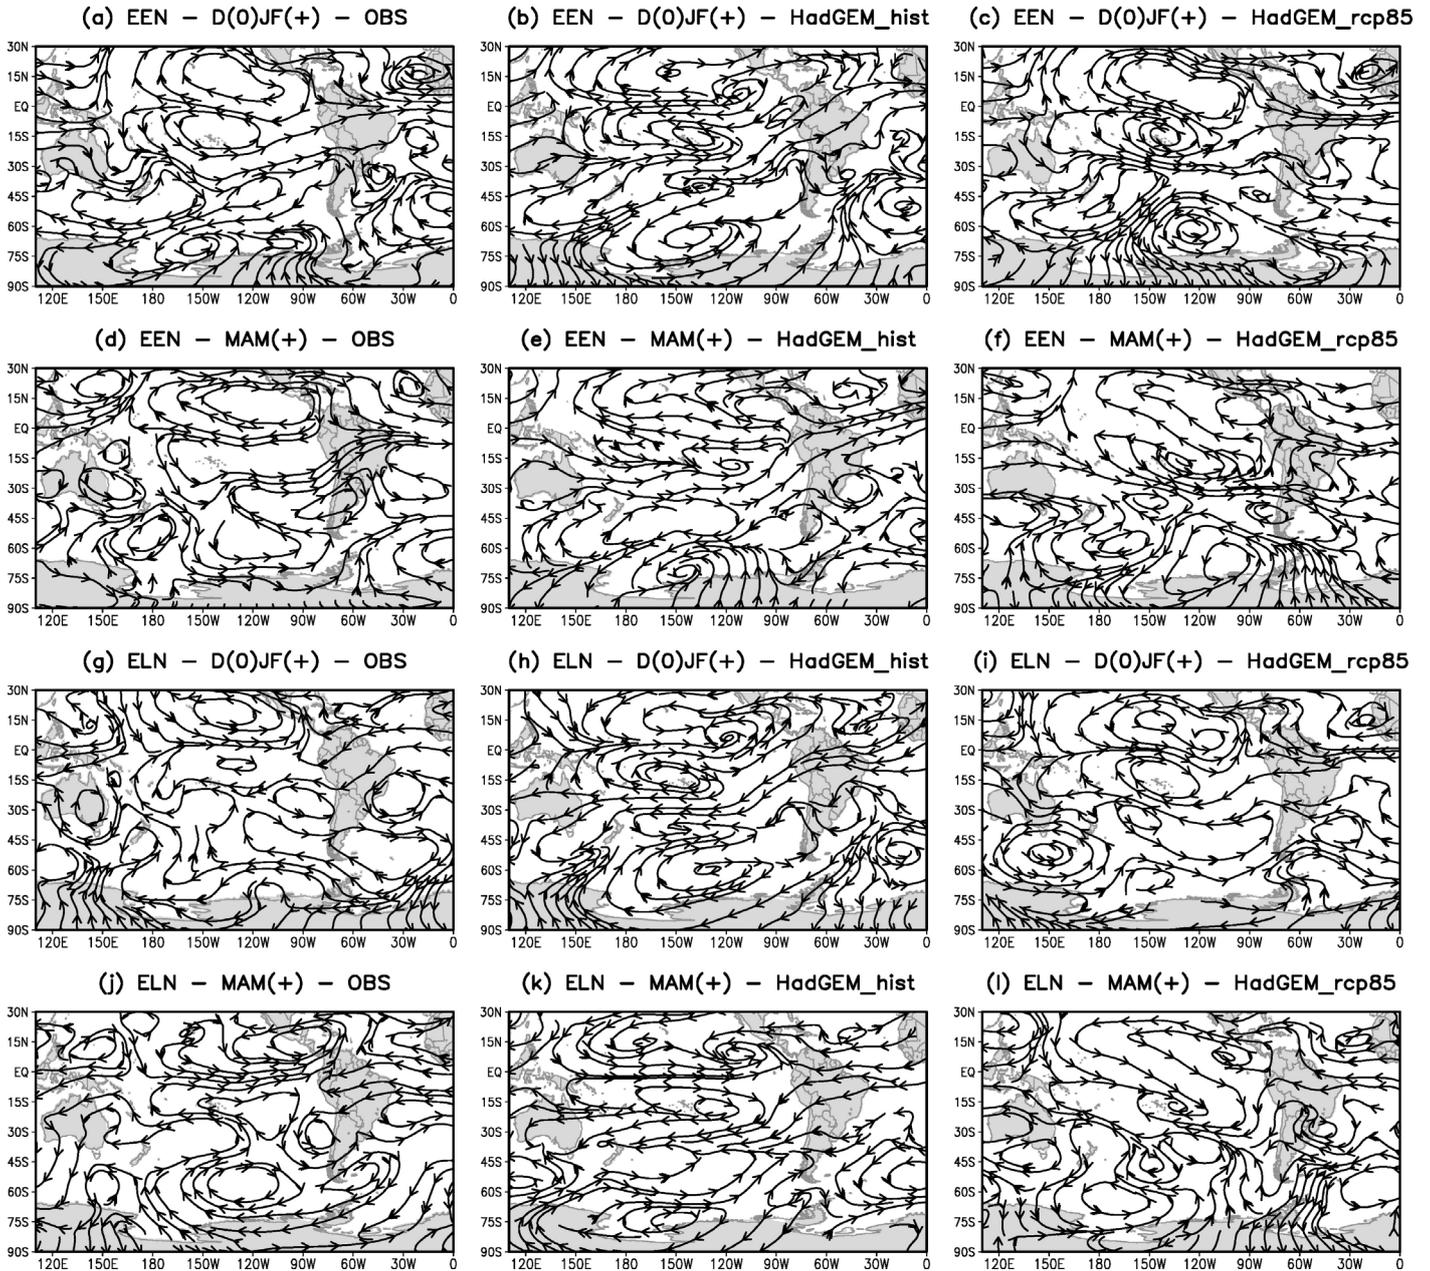

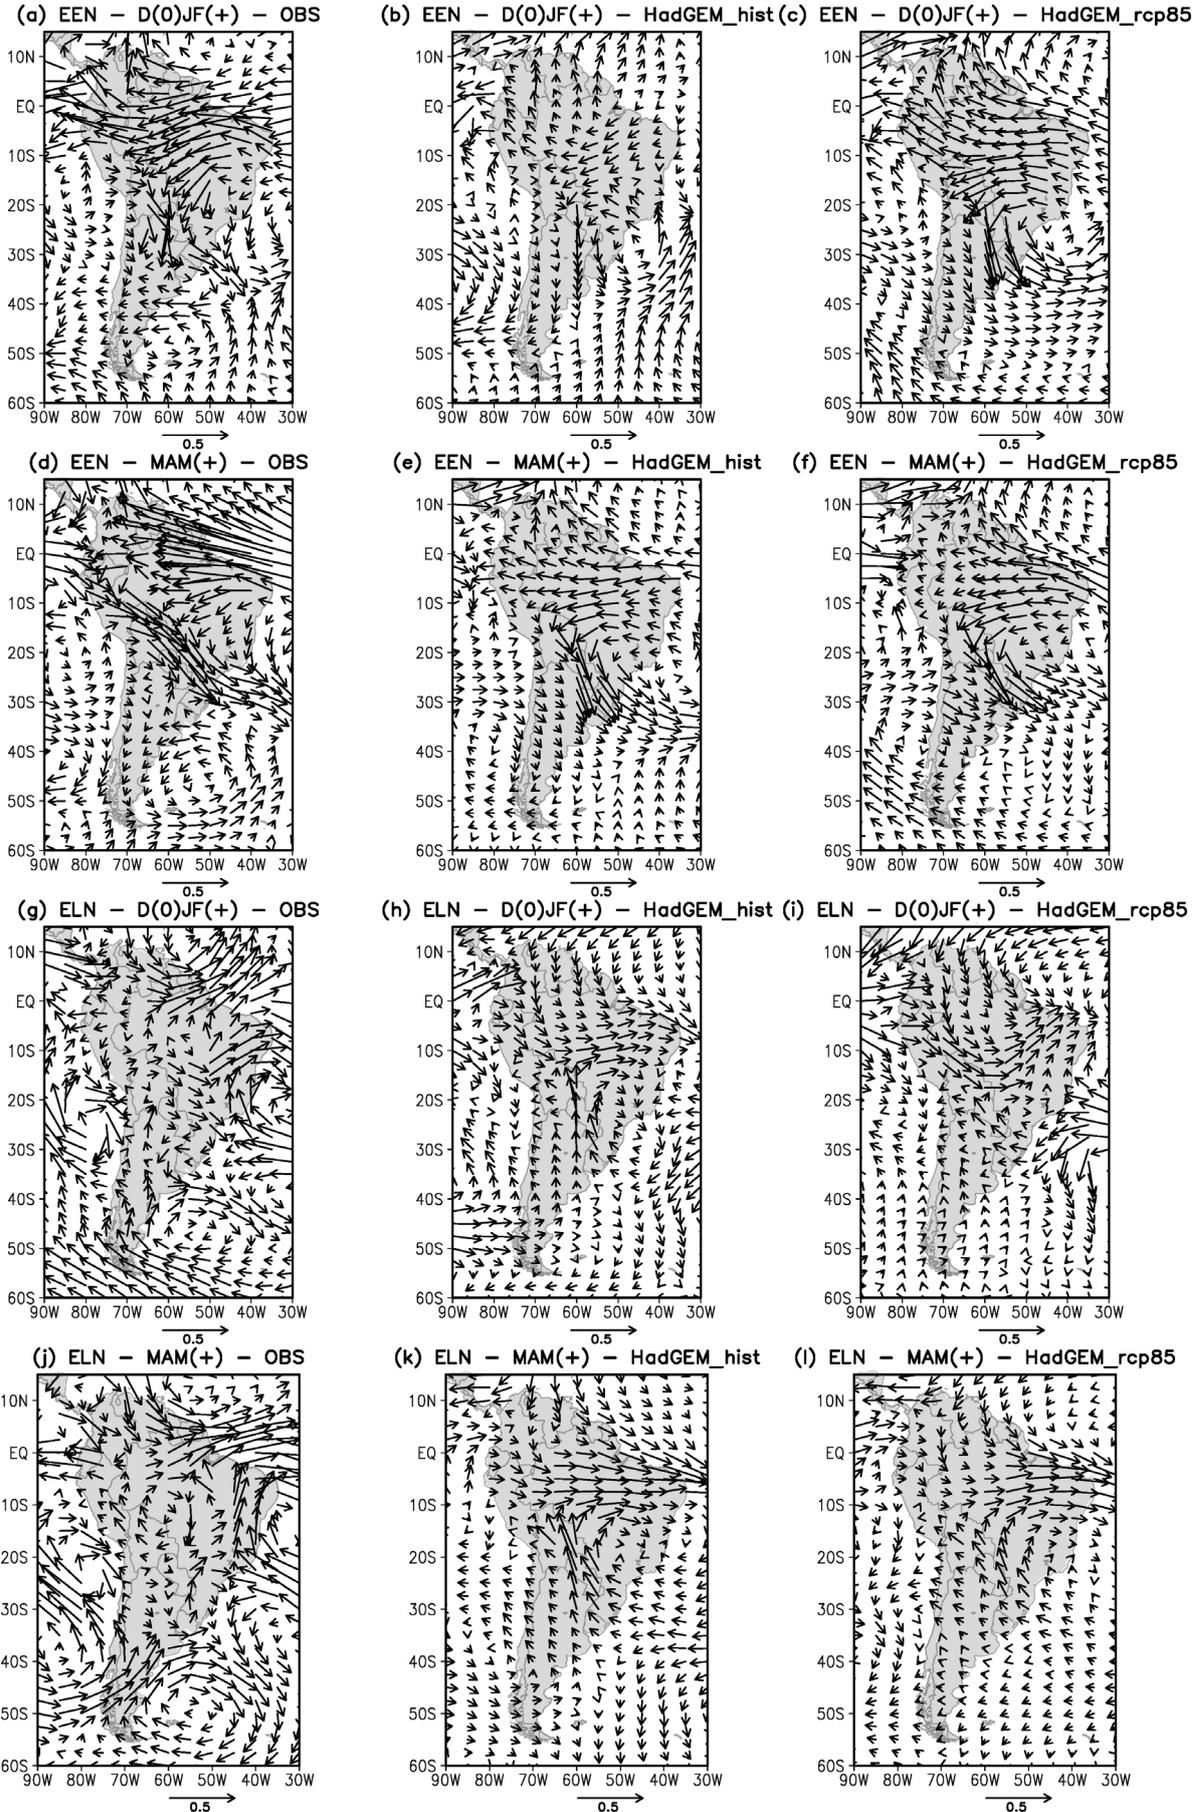

Fig. 5. Composites of streamline anomalies at 200 hPa during eastern El Niño (EEN) [D(0)JF(+)] (a–c) and MAM(+)] (d–f)] and eastern La Niña (ELN) [D(0)JF(+)] (g–i) and MAM(+)] (j–l)] based on observed data (left column), HadGEM2-ES in the historical period (center column), and HadGEM2-ES in the RCP8.5 scenario (right column)

torical period is related to the increase in moisture flux in the atmosphere, as discussed below. The high level circulation changes over tropical South America result in expansion, to the south, of the area with negative precipitation anomalies (Fig. 4).

The anomalies of moisture flux in EEN (Fig. 6), in the simulation and projection, show the increase in moisture flux from the Amazon region to the southeast of the continent in both D(0)JF(+) and MAM(+) in the future climate. Although weaker in the historical run

Fig. 6. Composites of anomalous vertically integrated moisture flux ($10^{-2} \text{ kg m s}^{-1}$) during eastern El Niño (EEN) [D(0)JF(+)] (a–c) and MAM(+)] (d–f)] and eastern La Niña (ELN) [D(0)JF(+)] (g–i) and MAM(+)] (j–l)] based on observed data (left column), HadGEM2-ES in the historical period (center column), and HadGEM2-ES in the RCP8.5 scenario (right column)

than in the observations, the model simulates this flux, which increases the precipitation over the south-east region. The increase in moisture flux southward in the future contributes to the precipitation increase over the LPB. Over the northern/northeastern parts of the continent, the moisture flux anomalies westwards also increase in the future climate.

3.3.2. ELN

During La Niña, negative anomalies are observed in small areas of the LPB, mainly during MAM(+) of ELN (Fig. 4j). The model indicates dry conditions over the middle/lower LPB and wet conditions over the northeast in D(0)JF(+) and MAM(+). This dipole of precipitation (decrease in southeastern and increase in northeastern South America) occurs only during MAM in the observations. During this season, under a warming scenario, the model still shows dry conditions over the LPB, but the positive anomaly over northeastern South America turns to normal conditions.

The streamline anomalies display the typical pair of cyclonic circulation around the equator over the Pacific during La Niña, in both model results and observations during summer and autumn (Fig. 5g–l). The model also reproduces the easterly anomalies over tropical South America, but the 2 anticyclonic circulations over the southwestern and southeastern coasts of the continent are weakly simulated.

The anomalies of moisture flux in ELN (Fig. 6) simulated during D(0)JF(+) and MAM(+) are weaker than the observed ones and show a moisture flux anomaly northwards over LPB, which explains the dry conditions in this region. This feature does not exist in observed ELN. Therefore, simulated and observed patterns have the same sign in composites of precipitation anomalies in ELN, but the mechanisms that cause the anomalies are different—in the observations, the cause is the circulation over the region, whereas in the simulation, it is associated with the simulated moisture divergence. The future projections during MAM(+) show a reduction in moisture flux towards the LPB (anomalous northward moisture flux), which is consistent with the decreased precipitation during ELN.

4. FREQUENCY OF EXTREME EVENTS

The maps of the differences in the frequency of extreme events between EEN and neutral years, both observed (Fig. 7a,d) and simulated by the

HadGEM2-ES model (Fig. 7b,e), show the expected pattern, viz. an increase in southeastern and a decrease in northern/northeastern South America (Grimm & Tedeschi 2009). Notwithstanding, there are important differences between the model and observations, especially in northeastern Brazil, in MAM, where the reduced frequency of extreme events is not well simulated by the model (Fig. 7d,e). Therefore, the projection cannot be assessed for that region. Over the LPB, the difference in the frequency of extreme events between EEN and neutral years in future projections (Fig. 7c,f) shows the same general features of the historical period, but more similar to the observed variations, between EEN and neutral years (Fig. 7a,d). The main difference with respect to the present climate is the strongest increase in extreme events in southeastern South America.

Fig. 7g–l presents the differences between the frequency of extreme events during ELN and neutral years. The observed patterns in DJF and MAM are different. HadGEM2-ES can reproduce the anomalies in parts of northeastern Brazil (more extreme events) and in parts of the LPB (less extreme events) in MAM(+) during ELN. During D(0)JF(+) of ELN, there is a strong decrease in the frequency of extreme precipitation events over northeastern South America in the observed data, while the simulated pattern shows an increase.

The differences between ELN and neutral years in the future projections are small compared to the historical period in MAM(+). As in precipitation composites, HadGEM2-ES cannot reproduce the pattern of extreme precipitation events in ELN during D(0)JF(+). Thus, the future projection cannot be evaluated.

5. DISCUSSION AND CONCLUSION

The HadGEM2-ES has difficulty in reproducing Central ENSO, since it indicates an average of 2 CEN and 1.75 CLN, while 6 and 8 cases were observed, respectively. This agrees with other studies showing that coupled models have difficulty in representing different types of ENSO (Ham & Kug 2012, Kug et al. 2012, Xu et al. 2014). In future projections, the number of central Pacific episodes is even lower, with just 0.5 CEN and 0.75 CLN. This disagrees with results from CMIP3 models that showed an increase in the frequencies of Central ENSO in future projections (Yeh et al. 2009). Our results indicate that the HadGEM2-ES model cannot be used to study different types of ENSO following the present method-

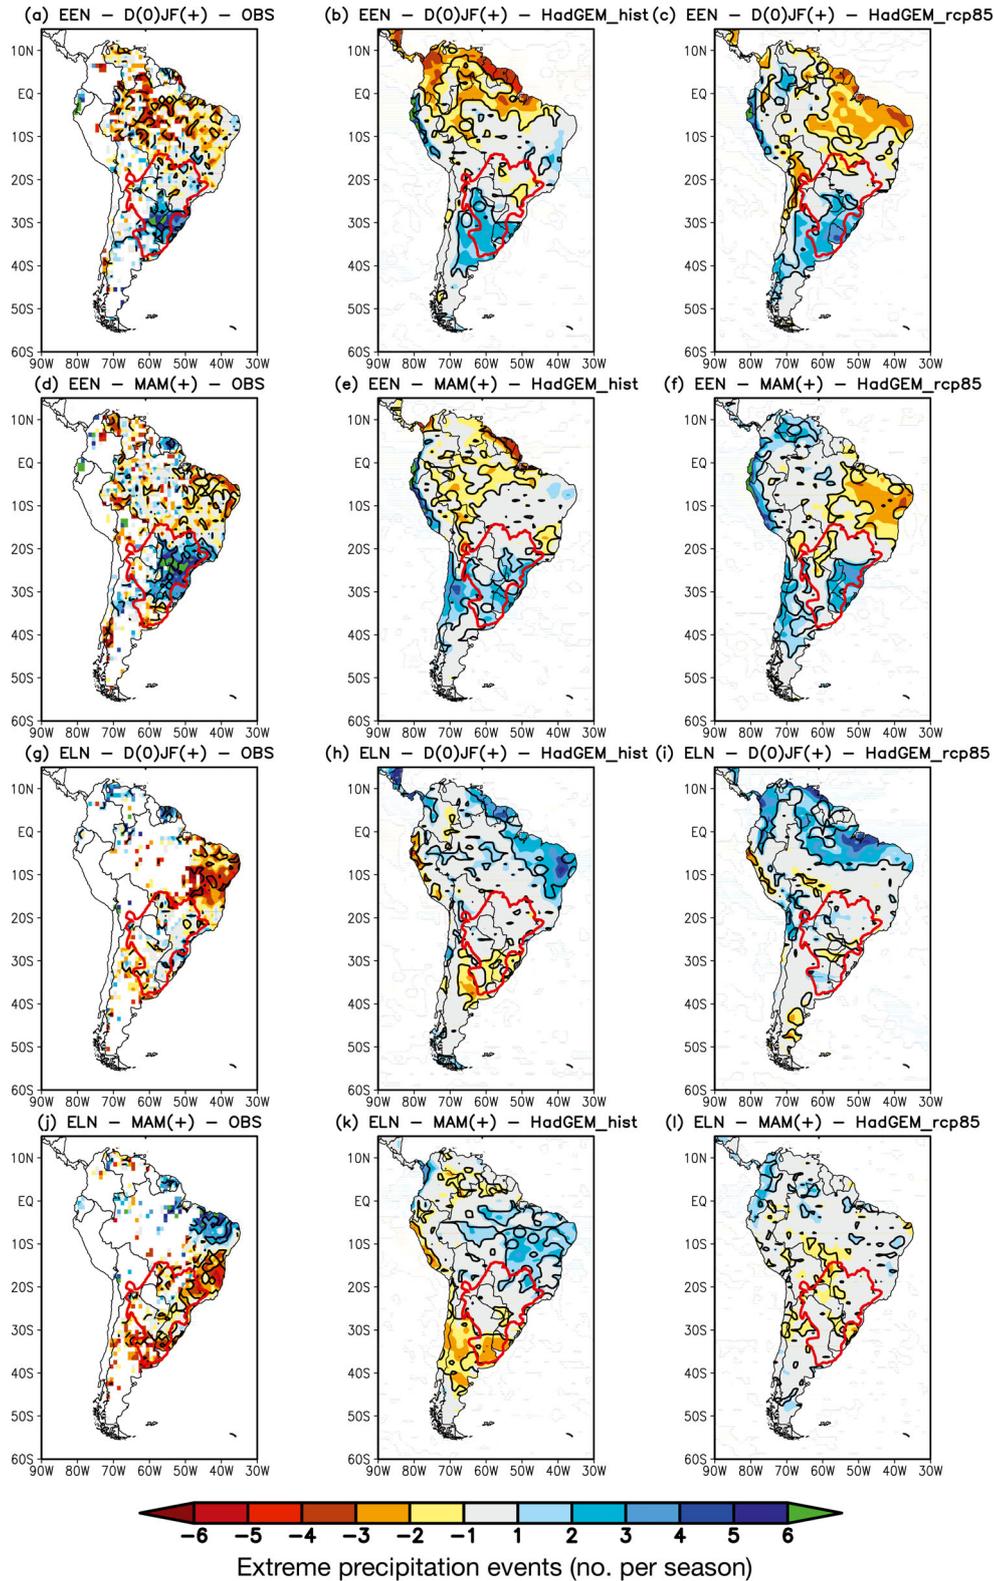

Fig. 7. Difference in the frequency of extreme precipitation events (events per season) between Eastern El Niño (EEN) and neutral years [D(0)JF(+)] (a–c) and MAM(+) (d–f)] and between Eastern La Niña (ELN) and neutral years [D(0)JF(+)] (g–i) and MAM(+) (j–l)] based on observed data (left column), HadGEM2-ES in the historical period (center column), and HadGEM2-ES in the RCP8.5 scenario (right column). Regions with positive (negative) anomalies higher (lower) than 1.0 (–1.0) event mo^{-1} and with a level of confidence >90% are outlined with a thick black line. The position of La Plata Basin is outlined in red

ology. However, it can reproduce the frequency of Eastern ENSO and can be used to study features of the South American precipitation during these events, in both historical simulations and in projections under a warming climate scenario. The inability of the model to reproduce Central ENSO and its impacts on South America might be related to the existence of unmodeled interdecadal climate variations, which are also responsible for interdecadal variations in model skill, even apparent in the atmospheric responses to ENSO (Grimm et al. 2006).

The patterns of SSTA were well represented in composites during Eastern ENSO in the historical simulations, but Central ENSO was well represented only in El Niño years. The simulated precipitation anomaly composites during EEN show the expected patterns for this category of years. The precipitation composites during ELN are well represented in the model only in MAM(+). In general, seasonal anomalies during La Niña were simulated less well than during El Niño.

In both seasons during EEN, precipitation anomaly patterns in the future are usually more similar to the observed patterns than those from the present climate simulation. They are more extensive and more intense in the future. On the other hand, during MAM(+) of ELN, future projections are weaker than simulated patterns. The model cannot reproduce the precipitation patterns in most areas of South America in ELN during D(0)JF(+) and thus, these patterns cannot be analyzed in future projections.

The frequencies of extreme events over the LPB are well represented by the model during D(0)JF(+) and MAM(+) in EEN and only during MAM(+) in ELN years. The patterns of the frequency of extreme events in projections of the future during EEN and ELN generally are similar to those simulated in the historical period, only with a greater extension and greater intensity, except for ELN during MAM(+).

The physical mechanisms for the precipitation anomalies over the LPB are related to the atmospheric circulation anomalies over South America and wave trains over the Pacific Ocean triggered by anomalies associated with ENSO, and are also related to the anomalous moisture flux over South America. Streamlines at 200 hPa composites were generated to show the Rossby wave trains and their contribution to the anomalous precipitation in extratropical South America (Grimm 2003, 2004, Tedeschi et al. 2013, 2015). The model represents the wave trains during EEN, which can result in good representation of precipitation patterns over southeastern South America. However, during ELN, the compos-

ites of streamline anomalies at 200 hPa present weaker anomalies over southeastern South America, and the simulated dry conditions over the LPB are related to the reduction in moisture flux over that region. The model represents the moisture flux increase from the Amazon region towards LPB in EEN, but the simulated patterns are weaker than the observed patterns. Simulated moisture flux patterns in ELN are opposite to those in EEN, as in the observations, but there are differences between model and observations that prevent the model from reproducing the precipitation pattern in this ENSO category in DJF.

Tedeschi & Collins (2016) studied the influence of 2 types of ENSO (Canonical and Modoki+A) on South American precipitation in different CMIP5 models. They showed that these models can represent both influences on tropical South America, but they have difficulty in representing the influences on central and southeastern South America. When we compared their results for HadGEM2-ES (figures not shown) with our results, we noted fewer cases for Modoki+A ENSO than for Central ENSO in the observed data, but the historical HadGEM2-ES simulation showed Modoki+A ENSO frequency similar to observations. In contrast, the frequency of Central ENSO (Table 1) in HadGEM2-ES results is lower than in the observed data. However, SSTA and precipitation anomaly patterns in these 2 different definitions of ENSO are similar, but during Canonical and Modoki+A ENSO, the magnitude is larger than during Eastern and Central ENSO. As in this study, HadGEM2-ES revealed precipitation patterns during Canonical and Modoki+A ENSO stronger in the future than in the present. Thus, if we change the methodology to define different types of ENSO years, the patterns may show small differences when applying one or the other methodology, but both methodologies show a strengthening in the future patterns.
