**ABSTRACT:** Poor water quality is discussed as a major factor causing a decline of brown trout populations in Swiss rivers. For our study we have chosen a river in the Swiss midlands, where the brown trout population has decreased dramatically during the last 10 yr and where feral fish have shown distinctive pathological alterations. The objective of our study was to investigate whether river water may be responsible for impaired fish health leading to an increased mortality in the river. In an active monitoring program, groups of brown and rainbow trout were exposed to polluted river water for 24 mo. Fish held in tap water served as a reference. Mortality, macroscopic and histopathologic changes, and infectious agents were investigated. Compared with the reference group, high mortality rates and severe pathological alterations of the inner organs were observed in fish held in river water. Especially gills, liver and kidney of these fish showed significantly higher changes than fish from tap water. These changes were dominated by degenerative and inflammatory reactions. Additionally, several infectious agents were diagnosed in fish exposed to river water. The most important findings were furunculosis and proliferative kidney disease. Brown trout seemed to be more sensitive than rainbow trout to environmental stress and infectious agents.

**KEY WORDS:** River water · Brown trout · Rainbow trout · Mortality · Infectious agents · Morphological changes

### INTRODUCTION

Declining brown trout populations have become a severe problem in many Swiss rivers over the past few decades (Frick et al. 1998, BUWAL 1999). The reasons for this decline are unclear. Water pollution and sewage plant inflows are discussed as possible contributors (Escher et al. 1999, Schmidt et al. 1999, Bernet et al. 2000). The river Langeten in the Swiss midlands is a typical example of a river in which brown trout populations have decreased over the past years (Fishing statistics 1990–1998, unpubl. data). Especially during the summer months, dead or weak brown trout could be seen downstream of sewage plants. Therefore, this river was chosen to evaluate the influence of the water quality on fish health. In a first study we examined the effect of treated waste water from 1 of the 3 sewage plants located along this river on the health status of brown and rainbow trout. Changes found in these trout were compared with alterations present in wild fish (Schmidt et al. 1999). Trout exposed to sewage effluents diluted with tap water showed only mild alterations in the inner organs, particularly degenerative liver changes (Schmidt et al. 1999). These results did not correspond to the findings in wild brown trout.
organic pesticides were above 20 µg l–1. For example, of treated water effluents, the concentrations of all in 2 out of 4 sampling dates of pooled weekly samples (Bern [GBL unpubl. data). At 1 sewage plant (Lotzwil), (Water and Soil Protection Laboratory of the district of experiment were still present in the river sediment were in the range of 1.6 to 4 µg l–1, galaxolides 0.1 to addition, nonylphenol and nonylphenol-ethoxylates were found in the river downstream of a sewage plant (Ochsenbein 1997). After technical changes were made in the factory applying permethrin, the concentrations in the river decreased significantly; however, concentrations up to 40 µg kg–1 at the location of our experiment were still present in the river sediment (Water and Soil Protection Laboratory of the district of Bern [GBL unpubl. data). At 1 sewage plant (Lotzwil), in 2 out of 4 sampling dates of pooled weekly samples of treated water effluents, the concentrations of all organic pesticides were above 20 µg l–1. For example, the following maximal concentrations were detected: atrazine 20 mg l–1, isoproturon 37 µg l–1, ethosulfuron 1.15 µg l–1, diazinon 0.8 µg l–1, metalaxyl 0.6 µg l–1, diethyltoluamide 0.7 µg l–1 and simazine 0.6 µg l–1. In addition, nonylphenol and nonylphenol-ethoxylates were in the range of 1.6 to 4 µg l–1, galaxolides 0.1 to 0.3 µg l–1 and anionic tenside 0.1 to 0.7 mg l–1 (Gerecke et al. 2001, U. Ochsenbein pers. comm.).

The question arose as to which factors are responsible for or contribute to the changes found in wild fish in the Langeten. Since infections and contaminants can cause organ alterations (Bucke 1993, 1997) and these alterations may cause death and, subsequently, population declines, emphasis was put on this hypothesis. The mode of action of environmental contaminants is either direct chemical or physical damage to cell membranes or tissues (e.g. Mallat 1985, Myers et al. 1992, 1994, Johnson et al. 1993), modification of physiological and biochemical reactions (e.g. Svobodova et al. 1994, Bucheli & Fent 1995), increased infection pressure by facultative pathogens (e.g. Khan & Thulin 1991, Koskivaara et al. 1991, Bernet et al. 2001) or reduced resistance to infection (e.g. Sindermann 1979, Aaltonen et al. 1997, Arkoosh et al. 1998).

Thus, the aim of our study was to identify possible causes of the observed alterations in fish from the river. Therefore, the following questions were posed: (1) Could the observed changes of the health status be responsible for the fish decline? (2) Do seasonal differences occur that may be correlated to parasitic infestation pattern and that would allow a correlation between parasitic infestation and impaired health status? (3) Do differences between river water-exposed and sewage water-exposed trout, or differences between river water-exposed and wild trout occur that may give further hints on the causes of impaired health status and fish decline? (4) Are there species-specific differences between brown and rainbow trout?

This last question is of interest because a recent debate in Switzerland dealt with a possible higher resistance of rainbow trout to environmental impact, an argument for stocking rivers with this non-native species. On the other hand, rainbow trout is assumed to compete effectively with brown trout. At present the release of rainbow trout into Swiss river systems is forbidden (GScG 1991).

**MATERIALS AND METHODS**

The experiments were carried out over a period of 24 mo (May 1996 through April 1998). The river examined (Langeten) is situated in the western midlands of Switzerland. Although brown trout are stocked in the Langeten every year, electrofishing revealed decreasing numbers of fish along the course of the river (Fishing statistics 1990–1998, Inspectorate of Fisheries of Bern unpubl. data), particularly below the last of 3 sewage treatment plant discharges situated along the river. According to physicochemical and biological (saprobiol- and algae-index system) examinations, the river is classified as moderately to critically polluted (AquaPlus 1994, VOKOS 1997). At the location of the experiment, the Langeten receives treated sewage effluents from 3 sewage plants and several agricultural areas. River water values measured during the experiment were water temperature, pH, oxygen concentration, dissolved organic carbon, biological oxygen demand, ammonia, nitrite, nitrate, total nitrogen, chloride, orthophosphate, total phosphorus, silicate, sulfate, sodium and potassium. Only values of ammonia occasionally exceeded the quality aims for running water in the winter months (GSChV 1998, GBL unpubl. data). For active monitoring, several trials of 60 brown trout (13 to 17 cm, 20 to 50 g) and 60 rainbow trout (19 to 22 cm, 70 to 110 g) from the stock culture at the Centre for Fish and Wildlife Health, University of Bern, Switzerland, were randomly assigned to groups and transferred to a 2000 l fibreglass tank. This tank was located at an area near the river Langeten (river water group) and supplied with river water by means of an...
open bypass. The different species, brown and rainbow trout, were separated by a perforated steel sheet (perforation diameter 1 cm). Water temperature ranged from 2 to 16°C over 1 yr (GBL unpubl. data). Oxygen concentration was ≥8 mg l⁻¹ during the study period. The reference brown trout and rainbow trout were held in tap water at the Centre for Fish and Wildlife Health in analogous tanks (200 trout per tank) with a constant flowthrough (20 l min⁻¹) of commercial tap water (reference group). Water temperature ranged from 13 to 17°C and oxygen concentration was ≥8 mg l⁻¹. All fish were fed commercial trout pellets (HOKOVIT, Bützberg, Switzerland) with a daily food ration equal to 1 to 2% of body weight. The mortality rate was recorded daily.

Fish in river water were first sampled in July 1996, after which time fish were routinely collected every 3 mo. Five brown trout and 5 rainbow trout were collected at each sampling. Additional samplings with at least 3 fish were carried out in cases of high mortalities. Fish had to be replaced several times (Table 1); however, this does not imply replication of the trials. Reference fish were collected every 6 mo. Fish were killed in buffered 3-aminobenzoic acid ethyl ester (Argent Chemical Laboratories, Redmont, USA). Immediately after death, blood was collected from the caudal vein. After centrifugation (3600 × g for 10 min at 4°C) the serum was stored at −80°C until further investigation (up to 3 mo). Antibodies against the virus of the viral hemorrhagic septicemia were measured according to Meier & Wahli (1988). Trout were weighed and measured individually. A standard necropsy was performed. Virologic, bacteriologic and parasitologic examinations were performed as described by Schmidt et al. (1999). Pieces of skin (excised cranial of the dorsal fin), gills, liver and kidney from all animals were fixed in Bouin fixative for 24 h, routinely processed for histology and stained with hematoxylin and eosin, periodic acid-Schiff, and, if indicated, van Gieson stains. Histopathologic changes were described qualitatively and alterations were quantitatively evaluated according to an assessment tool (Bernet et al. 1999). According to the degree and extent of lesions, an organ index for each organ was determined. The sum of these organ indexes resulted in a total index for the individual fish (Tot_I). Parasites in the inner organs were examined by histology; 2 to 3 different histologic sections were investigated. To distinguish Sphaerospora sp. from sporogenic stages of PKX cells, a histochemical staining procedure using biotinylated GS-1 lectin (Griffonia simplicifolia agglutinin-1) as described by Marin de Mateo et al. (1993) was performed. PKX cells were recently identified as myxosporeans belonging to Tetracapsula n. sp. (Canning et al. 1999, Saulnier et al. 1999, Kent et al. 2000).

Fish that were found dead in the tanks were, if possible, examined for infectious agents and macroscopic changes as described above.

The data of the histopathologic evaluation were checked for normal distribution using Lilliefors test and normal probability plot. Differences between non-normally distributed data were tested using the Mann-Whitney U-test. For histopathologic alterations, relative risk (RR) values were calculated by dividing the prevalence of changes of the exposed brown trout and rainbow trout, respectively, by the respective prevalence of the reference brown and rainbow trout. These were tested using χ²-test according to Pearson, Mantel and Haenszel (Sachs 1997). Differences in parasite prevalence and differences in the abundance of sacciform cells in the skin between the river water and reference groups and between the brown and rainbow trout were tested using χ²-test. Relations between the season or the exposure time and the histopathologic changes or the prevalence of parasites were determined using Spearman’s test of correlation. The level of significance of all statistical tests was set at 5% with Bonferroni-adjustments. All statistical analyses were calculated using the SYSTAT program (v8.0, SPSS Inc., Chicago, USA).

Table 1. Stocking and samplings of river water-exposed brown and rainbow trout. Number of introduced fish and exposure time in months at sampling are given. Numbers of fish sampled are shown in parentheses. –: no fish left because of high mortality rate

RESULTS

Mortality

No mortality occurred in the reference fish held in tap water. In contrast, high mortality rates occurred in fish exposed to river water (Fig. 1); the rate was clearly higher in brown trout than in rainbow trout (Fig. 1). Especially in the summer months (July to October) the mortality rate was elevated. Mortality rates also differed between years: the highest rates were seen in 1996.

Macroscopic findings

In the reference animals no macroscopic changes were found.

Brown and rainbow trout held in river water showed mild ulceration of the upper and lower jaw and several fish showed skin erosions and ulcers.

In the inner organs, changes in the spleen, liver and kidney were most obvious. Especially in July and August splenomegaly, proliferative nephritis and multiple areas of necrosis in the liver were diagnosed macroscopically. In the other months these changes occurred only occasionally.

Table 2. Values (median) of the histological total index for the individual fish (Tot_I), circulatory, degenerative, proliferative and inflammatory index, and gill, skin, liver and kidney index of brown and rainbow trout; quartiles are shown in parentheses (25%/75%); the percentage increase of indexes of exposed fish compared with indexes of reference fish of the same species are given. *Significant differences of indexes of the river water group compared with the reference group (Mann-Whitney U-test; p < 0.05)

Histologic findings

Brown trout

According to the Tot_I, brown trout held in river water showed significantly more severe histopathologic alterations than reference fish (Mann-Whitney U-test, U = 271.5; p = 0.003) (Table 2). Components of the Tot_I are circulatory changes, degenerative changes, proliferative changes, inflammatory changes and neoplasms. Degenerative changes (Mann-Whitney U-test, U = 288; p = 0.005), proliferative changes (Mann-Whitney U-test, U = 275; p = 0.003) and inflammatory changes (Mann-Whitney U-test, U = 166.5; p < 0.001) differed significantly between the reference and exposed groups. Indexes of all 4 organs (gill, skin, liver and kidney) were elevated in the exposed group; however, significant differences were seen only in liver values (Mann-Whitney U-test, U = 133.5; p < 0.001).

Fig. 1. Mortality rate of river water-exposed brown and rainbow trout. Mortality was calculated at the end of every trial. Percentage of mortality per trial is given. Exposure time in months shown in parentheses.
There was no significant correlation between exposure time and the Tot_I values or the organ indexes of the brown trout held in river water (Spearman correlation, n = 43; p > 0.05). There was, however, a significant correlation between the season and the Tot_I values (Spearman correlation, r_s = 0.709; p < 0.001) and the organ indexes (Spearman correlation, n = 43, r_s_gill = 0.573, r_s_skin = 0.362, r_s_liver = 0.576, r_s_kidney = 0.673; p < 0.05).

**Gills.** Plasma alterations, such as granulated eosinophilic cytoplasm or vacuolation, epithelial cell lifting and hyperplasia of the epithelial cells, were more prevalent and more pronounced in the river water group than in the reference group. Multifocal necrosis of the gill epithelial cells occurred only in the river water group. Compared with the reference fish, the river water-exposed trout showed a significantly higher RR for epithelial cell lifting (RR = 1.8; χ² = 6.7; p < 0.01), hyperplasia (RR = 1.2; χ² = 6.7; p < 0.01) and necrosis of epithelial cells [RR = * (cannot be evaluated because the reference value is 0); χ² = 14.1; p < 0.001].

Epitheliocystis caused by a chlamydia was diagnosed only in the river water-exposed brown trout. These epitheliocystis cysts showed no surrounding inflammatory reaction.

**Skin.** Brown trout exposed to river water showed a higher prevalence and abundance of multifocal skin erosions and ulcers than reference fish. Most of these alterations were accompanied by a mild, mainly lymphocytic infiltration of the surrounding tissue. The number of sacciform cells in the epidermis was significantly increased in the river water group (χ² = 4.9; p < 0.05). Further structural alterations included irregular structure of the basal cell layer.

**Liver.** Compared with the reference brown trout, the river water group showed an increased prevalence and severity of structural alterations, such as distended sinusoïds and separation of the liver cells, of plasma alterations, such as condensed eosinophilic or granulated cytoplasm, and of pericholangian and perivascular fibrosis and lymphohistiocytic infiltration. Increased numbers of necrotic single cells and small foci of necrosis were diagnosed in 35% of the river water-exposed brown trout. In 14% of the trout held in river water, *Tetracapsula n. sp.*, surrounded by a granulomatous infiltration, were found in the parenchyma. Brown trout of the river water group had a significantly increased RR of structural alterations (RR = 3.2; χ² = 8.9; p < 0.01), necrosis of the hepatocytes (RR = *; χ² = 10.2; p < 0.01), and infiltration with lymphocytes and single macrophages either around bile ducts and vessels or randomly distributed in the parenchyma (RR = 2.4; χ² = 25.4; p < 0.001).

**Kidney.** Brown trout exposed to river water showed a higher prevalence and severity of tubulonephrosis, deposits of desquamating tubular cells, hyalinous casts in the tubules and peritubular fibroblast proliferation. However, this increase was not significant (χ²-test, p > 0.05). Mild multifocal necrosis of interstitial cells occurred in 14% of the river water-exposed brown trout. Infection with *Tetracapsula n. sp.* was diagnosed in 35% of animals of the river water group. The extrasporogonic stages were associated with mild to severe proliferation of the interstitial tissue and granulomatous infiltration. Sporogonic stages in the tubules were not associated with an inflammatory reaction. Infection with *Sphaerospora* sp. in the tubules was also diagnosed only in the river water-exposed trout. Infection with these parasites was associated with only mild degenerative tubular changes in severe infestations.

**Rainbow trout**

Reference rainbow trout showed significantly lower Tot_I values than the river water group (Mann-Whitney U-test; U = 87.0; p < 0.001). According to the pattern of the changes, values of degenerative, proliferative and inflammatory alterations differed significantly (Mann-Whitney U-test; U = 151.0 [proliferative], U = 189.5 [degenerative], U = 208.0 [inflammatory]; p < 0.001). Gill, skin and kidney values of reference fish were significantly lower than those of exposed fish (Mann-Whitney U-test; U = 46.5 [gill]), U = 224.0 [skin], U = 198.5 [kidney]; p ≤ 0.001).

The lesions found in rainbow trout corresponded qualitatively to those found in brown trout. Rainbow trout of the river water group showed a significantly higher RR of plasma alterations of gill epithelial cells (RR = 3.3; χ² = 11.2, p < 0.001), hypertrophy of gill epithelial cells (RR = 1.6, χ² = 11.1, p < 0.001) and structural alterations of the skin (RR = 1.4, χ² = 11.2; p < 0.001), such as erosions, than reference fish. Similar to brown trout, only the river water-exposed rainbow trout were infected with *Tetracapsula n. sp.* (prevalence 26%), resulting in a higher RR to show structural alterations (RR = *; χ² = 7.6, p < 0.01) and infiltration of the kidney interstitium (RR = *, χ² = 12.3, p < 0.001). In 7% of the river water-exposed rainbow trout *Tetracapsula n. sp.* were also found in the liver parenchyma.

In the rainbow trout held in river water the season had a significant influence only on the development of kidney alterations (Spearman correlation, r_s = 0.338; p < 0.05).

**Infectious diseases**

**Virologic infections**

No viruses were isolated.
Bacteriologic findings

In the reference fish no bacteria were isolated. During the regular samplings 1 river water-exposed brown trout and 1 rainbow trout showed a systemic infection with *Aeromonas salmonicida*. But animals that were found dead between the samplings and that could still be examined bacteriologically showed a prevalence of furunculosis (infection with *A. salmonicida*) of approximately 50%.

Of the river water-exposed brown trout 21% showed an infection of the gills with epitheliocystis. Epitheliocystis infections did not occur in the other groups.

Parasitologic findings

*Brown trout.* In the reference fish no infestations with parasites were found except a low number of *Gyrodactylus* sp. in 4 animals. In contrast, 93% of the river water-exposed brown trout showed a parasitic infestation. The prevalence of fish infested with *Gyrodactylus* sp. also increased significantly over time in the river water-exposed fish ($\chi^2 = 4.74, p = 0.03$). On average the brown trout held in river water were infested with 2.2 parasite species per fish. The whole parasite fauna in the exposed brown trout consisted of 6 species: 4 species on the skin (*Gyrodactylus* sp., sessile peritrichia, *Trichodina* sp., *Ichthyophthirius multifiliis*) and 2 species in the kidney (*Tetracapsula* n. sp., *Sphaerospora* sp.). The prevalence and abundance of these parasites in the different groups are shown in Table 3. Significant seasonal differences were found. *Gyrodactylus* sp. was significantly more frequent in autumn ($\chi^2 = 10.0, p = 0.02$), *Tetracapsula* n. sp. in summer ($\chi^2 = 22.7, p < 0.001$), and *Sphaerospora* sp. in spring and summer ($\chi^2 = 18.5, p < 0.001$).

*Rainbow trout.* Skin of reference rainbow trout was slightly infested with *Gyrodactylus* sp. and *Trichodina* sp. Of the rainbow trout held in river water 76% showed a parasitic infestation. Compared with the reference fish, in the river water group the prevalence of *Trichodina* sp. infestations was significantly higher ($\chi^2 = 10.37, p = 0.001$) and the abundance was clearly elevated. On average river water-exposed trout were parasitized with 1 parasite species per fish. The whole parasite fauna of the river water-exposed rainbow trout consisted of 4 parasite species on the skin (*Gyrodactylus* sp., sessile peritrichia, *Trichodina* sp., *Ichthyophthirius multifiliis*) and *Tetracapsula* n. sp. in the kidney (Table 3). Only *Tetracapsula* n. sp. were significantly more frequent during the summer months ($\chi^2 = 41.2, p < 0.001$). Compared with brown trout, rainbow trout exposed to river water showed significantly lower prevalences in parasitic infestation with sessile peritrichia and *Sphaerospora* sp. ($\chi^2 = 24.08, p < 0.001$; $\chi^2 = 20.87, p < 0.001$).

**DISCUSSION**

The aim of the present study was to investigate the impact of water quality (river water compared with tap water) on the health status of trout in order to find possible explanations for the decline of brown trout populations. River water-exposed brown trout showed high mortality rates whereas in the reference fish no mortality occurred. Histopathological changes in the gills, liver and kidney, which may result in decreased vitality, were found in the river water group. Additionally, several exposed animals showed high infestation rates with primary and secondary pathogenic parasites. These findings indicate impaired fish health in river water-exposed animals. The pattern of histopathologic changes

*Significant seasonal differences ($\chi^2$ test; $p < 0.05$); *Significant differences to the reference ($\chi^2$ test; $p < 0.05$); *Significant species differences ($\chi^2$ test; $p < 0.05$)
changes in our study as well as the infestation rates with parasites were comparable with changes found in wild fish in the lower part of the river (Schmidt et al. 1999). Several histopathologic alterations correlated with infectious agents, e.g. granulomatous nephritis with PKD infection (Clifton-Hadley et al. 1987, Hoffmann & El-Matbouli 1994). Other lesions, such as pericholangiary and perivascular fibrosis, lymphocytic infiltration in the liver parenchyma and multifocal necrosis, could not clearly be assigned to a specific cause. These changes may either be part of a PKD infection or be directly induced by water ingredients as they were present in fish without PKD infection too. Lesions described here are also found in fish exposed to organic contaminants (Myers et al. 1992, Johnson et al. 1993) or to pesticides (Hinton et al. 1993, Burkhardt-Holm et al. 1998). In the gills no infectious agent causing lesions was isolated. The described changes, such as epithelial cell lifting, multifocal necrosis and epithelial hyperplasia, are not specific to one particular agent and can be induced by a range of different stressors including pesticides, heavy metals and low oxygen content (reviewed in Mallat 1985, Haya 1989). Comparable lesions were also described following exposure to wastewater (Carlone et al. 1987). Low concentrations of permethrin up to 40 µg kg⁻¹ at the location of our experiment were still present in the river sediment (GBL unpubl. data). Therefore, release of low amounts and chronic effects on the fish health might be possible. Whereas rupture and necrosis of epithelial cells are believed to be a direct effect of irritants, epithelial hyperplasia is interpreted as a defence response of fish (reviewed in Mallat 1985). All together, the impaired fish health in our study may indicate a decreased vitality of wild brown trout populations in the Langeten. Pollution with sewage effluents was discussed as one possible cause. However, in a previous study we showed that sewage water effluents of 1 sewage plant in its own did not cause mortality and fish showed only mild to moderate histopathologic changes in the liver (Schmidt et al. 1999). In this former study, fish were not exposed to infectious agents normally present in a river. Thus, pathogenic parasites may be important factors for the results of the present study.

In the reference brown trout only Gyrodactylus sp., and in the reference rainbow trout additionally Trichodina sp., were found in low abundance. These parasites were probably introduced with the stock fish. As reference fish were kept in tap water, an infestation with further parasite species via the water route was not likely.

In the river water-exposed trout the parasitic infestation was mainly limited to secondary pathogenic agents, such as the skin parasites and Sphaerospora sp. in the kidney. Additionally, Tetracapsula n. sp. was diagnosed in liver and kidney. A similar parasite fauna was found in wild fish with increasing prevalence and abundance of Tetracapsula n. sp. along the course of the river (Schmidt et al. 1999). A number of infectious diseases are known to be favored by environmental stress (reviewed in Sindermann 1979, Bucke 1997). Environmental stress can promote increased parasitism in fish because of a decreased host immune response (Khan & Thulin 1991, Poulin 1992, Nowak 1999) or direct effects on the parasite fauna (Voltonen et al. 1997). However, effects can also be dual: either pollution stress can influence the prevalence of parasites directly or indirectly, or the parasite infestation may decrease the host resistance to toxic pollutants (Sindermann 1979). Tetracapsula n. sp. was shown to be promoted by water contaminants (Hoffmann & Danschat 1981, Clifton-Hadley et al. 1984). This hypothesis was supported in the Langeten because prevalence of PKD in wild fish increased significantly along the course of the river (Schmidt et al. 1999). In our study, in both species a significant increase of PKD infections during the summer months was evident. As the Tetracapsula n. sp. cycle is temperature dependent, high summer temperatures have a positive influence on this parasite (Clifton-Hadley et al. 1984). Thus, the higher mortality rate in our tanks during the summer months might be caused partly by these PKD infections. Also in the river Langeten, especially during the summer months, a high mortality rate in wild immature brown trout was reported and all dead fish were found to harbor Tetracapsula n. sp. (Inspectorate of Fisheries of Bern pers. comm., and Schmidt-Posthaus et al. unpubl. data). PKD is known as a significant factor limiting salmonid production in Europe and North America (Hedrick et al. 1993) but there is little information about PKD in wild fish and its impact on wild populations (Feist & Bucke 1993). Longshaw et al. (1999) showed that bryozoans, presumably a further host in the life cycle of Tetracapsula n. sp., occur in rivers enzootic for PKD in the UK. The same species of bryozoans also occur in Swiss rivers (Frutiger, EAWAG, pers. comm.). We conclude that special stress conditions, such as high temperature, decreased water quality, and increased prevalence and abundance of secondary infectious agents, may favor infection with PKD leading to increased mortality rates in wild brown trout populations. To further examine the significance of PKD for Swiss brown trout populations, the distribution of PKD in Swiss rivers will be investigated in a larger surveillance and compared with population data (Burkhardt-Holm 2000).

Other than PKD, only secondary pathogenic parasites were found in the river water-exposed trout. Nevertheless, there was a clear increase in Gyrodactylus sp. prevalence and abundance in both river water
groups, brown and rainbow trout, compared with reference trout. In earlier studies we showed that Gyrodactylus sp. was favored by sewage plant effluents (Schmidt et al. 1999, Bernet et al. 2001). In river water-exposed brown trout, significant seasonal differences in Gyrodactylus sp. infestations (highest prevalence in autumn) were found. This can also result from direct influences of environmental factors, such as temperature, or a secondary increased replication rate because of a suppressed immune system of the host. It is known that temperature and oxygen content are the most important physical parameters for monogenea (Williams & Jones 1994). Two other secondary pathogenic parasites (sessile peritrichia and Trichodina sp.) were only observed in the river water groups or were significantly increased in these fish (Trichodina sp. on the skin of rainbow trout). It has been previously shown that both parasites can be favored by environmental pollution (Roberts 1989, Khan & Thulin 1991, Valtonen & Koskivaara 1994, Escher et al. 1999, Bernet et al. 2001).

From our results we conclude that Tetracapsula n. sp. is the most harmful among the parasite species found in this study.

A further infectious agent that may play a role is Aeromonas salmonicida, which causes furunculosis. Furunculosis is known to cause high mortality among salmonids (Roberts 1989). This disease was diagnosed in several fish found dead in our tanks. A. salmonicida can exist in carriers or as a latent infection that can develop into a disease outbreak if the fish are stressed (Snieszko 1974, Sindermann 1979).

A further aim of our study was to compare brown trout with rainbow trout with respect to their sensitivity to environmental stress and infectious agents. Compared to rainbow trout, exposed brown trout showed a clearly higher mortality rate. Histopathologically, the pattern of distribution of the alterations differs between the 2 species. River water-exposed brown trout showed increased liver alterations, whereas in river water rainbow trout, gill and skin changes were more pronounced. This was also shown in our previous study (Schmidt et al. 1999). Therefore, it has to be considered that the exposure time was not the same because of the above-mentioned increased mortality in brown trout. Qualitatively, changes such as gill epithelial necrosis, hepatocyte necrosis and infiltration were also more pronounced in brown trout. Furthermore, there were significant differences in the prevalence of 2 facultative pathogenic parasites (sessile peritrichia and Sphaerospora sp.). There were also species-specific differences in the prevalence of PKD, although these differences were not significant. PKD was more frequent in brown trout than in rainbow trout. Our results correspond to earlier findings by Pickering et al. (1989) and Schneeberger (1995), who showed that brown trout are more sensitive to stress situations, expressed as a higher incidence of bacterial and fungal infections and higher mortality rates caused by diseases. Nevertheless, both species showed a variety of changes indicating decreased water quality, which should be improved. Such an improvement may make stocking with rainbow trout unnecessary.

In conclusion, we showed that fish were exposed to various infectious agents under field conditions. Additional environmental stress, such as high temperature and low water quality, could have favored some primary pathogenic agents, such as Tetracapsula n. sp. and Aeromonas salmonicida, which could have led to increased mortality. Further studies have to evaluate the overall importance of these infectious agents in river systems with declining fish populations and whether the higher incidence of these agents correlates with a depressed immune system of the animals.

Acknowledgements. Thanks are due to Mr Eberhardt and Mr Wälchli for taking care of the fish and recording the mortality rates; the Water and Soil Protection Laboratory of the district of Bern (GBL) for providing data of water analysis; Mr R. Benguerel, Dr G. Lamche, Mrs L. Lagcher and E. Oldenberg for assistance during the samplings; as well as to the laboratory of histology of the Institute of Animal Pathology. Thanks are due to Mrs U. Forster for excellent technical assistance in histochemistry. This work was supported by the Swiss Federal Agency for Environment, Forests and Landscape, the Inspectorate of Fisheries of Bern, the GBL and the Swiss National Science Foundation (3100-045894.95/1).
