ABSTRACT: Picophytoplankton (≤3 µm) are major contributors to plankton biomass and primary productivity in the subtropical oceans. We examined vertical and temporal variability of picophytoplankton primary productivity at near-monthly time scales (May 2012–May 2013) in the North Pacific Subtropical Gyre (NPSG) based on filter size-fractionated and flow cytometric sorting of radiolabeled (^{14}C) picoplankton cells. Primary productivity by picophytoplankton comprised ~68 to 83% of total (>0.2 µm) particulate ^{14}C-based productivity, and was lowest between September and December and highest between March and August. Group-specific rates of production by *Prochlorococcus*, *Synechococcus*, and photosynthetic picoeukaryotes (PPE) averaged ~39, ~2, and ~11% of the total ^{14}C-productivity, respectively. Average cell-specific rates of production by PPE (15.2 fmol C cell^{-1} d^{-1}) were 25- to 90-fold greater than *Prochlorococcus* (0.36 fmol C cell^{-1} d^{-1}) and *Synechococcus* (1.56 fmol C cell^{-1} d^{-1}). *Prochlorococcus* dominated (61–78%) the summed picophytoplankton biomass, while PPE and *Synechococcus* contributed 21–36% and 2–8%, respectively. Rates of production normalized to biomass were nearly equivalent amongst *Prochlorococcus*, *Synechococcus*, and PPE, averaging 0.6, 0.5, and 0.4 d^{-1}, respectively. Over our study period, *Prochlorococcus* and PPE production varied 4- to 5-fold, while biomass varied ~3-fold. In contrast, *Synechococcus* production varied ~30-fold, with peak rates in March 2013 accompanied by ~13-fold increase in biomass. Combined, our results provide evidence for rapid growth by picophytoplankton in this persistently low-nutrient ecosystem, highlighting the importance of cell loss processes responsible for mediating organic matter cycling in the euphotic zone of the NPSG.

INTRODUCTION

Picophytoplankton (≤3 µm) are dominant contributors to plankton biomass and net global productivity, particularly in the oligotrophic subtropical ocean gyres (Sieburth et al. 1978, Marañón et al. 2001, Carr et al. 2006). In the North Pacific Subtropical Gyre (NPSG), one of the largest ocean ecosystems on Earth (Sver-

drup et al. 1946), persistent thermal stratification of the upper ocean and a relatively deep, permanent pycnocline largely prevent nutrient-enriched deep waters from penetrating the euphotic zone (Eppley et al. 1973, Karl & Lukas 1996). The combination of stratification and perennially high photosynthetically active radiation (PAR) promotes active consumption of available nutrients by phytoplankton, resulting in persistently low concentrations of inorganic nutrients throughout the upper ocean. As a result, a large fraction of primary productivity appears to be sustained by the rapid recycling of nutrients through microbial food webs (Karl 2002).

A diverse assemblage of picoplankton, including photosynthetic picoeukaryotes (PPE) and cyanobacteria belonging to the genera *Prochlorococcus* and *Synechococcus*, dominate (60–90%) phytoplankton biomass and account for >70% of net primary production in the NPSG (Campbell & Vaulot 1993, Vaulot et al. 1995, Li et al. 2011). The significant contributions of picophytoplankton to biomass and primary production appear linked to efficient nutrient acquisition and light-harvesting capabilities (Takahashi & Bienfang 1983, Raven 1986, Chisholm 1992, Raven 1998). Amongst the picophytoplankton, cellular abundances of *Prochlorococcus* are typically orders of magnitude greater than those of *Synechococcus* or PPE in the NPSG, and past studies have largely focused on understanding the controls on cyanobacterial growth rather than their eukaryotic counterparts (e.g. Campbell & Vaulot 1993, Campbell et al. 1994, Liu et al. 1995, Björkman et al. 2015). However, studies from the subtropical Atlantic Ocean have reported high cell-specific rates of ^{14}C primary production by PPE, making them potentially significant contributors to carbon fixation (Li 1994, Jardillier et al. 2010). Moreover, studies in the North Atlantic indicated that a large fraction of PPE growth may be supported through assimilation of nitrate (Fawcett et al. 2011, 2014), making these picoplanktonic organisms potentially important contributors to new production.

Since 1988, the Hawaii Ocean Time-series (HOT) program has measured a suite of properties and processes to characterize ocean physics and biogeochemistry on near-monthly time scales at Station ALOHA (22.75° N, 158° W), a site representative of the NPSG (Karl & Lukas 1996). The resulting measurements have proven invaluable for characterizing temporal dynamics of bioelemental stocks and fluxes in this ecosystem. For example, the HOT program measurements of ^{14}C-based primary productivity reveal seasonal variations that co-vary with changes in solar radiation (Karl & Church 2014). Superimposed

on this seasonal dynamic are annually recurring summertime phytoplankton blooms, whose occurrences are often linked to episodic mesoscale events such as eddies (Dore et al. 2008, Church et al. 2009) and appear to be large contributors to particulate carbon export to the deep sea (Karl et al. 2012). In addition, temporal variations in light appear to have a significant impact on the dynamics of nutrient drawdown and subsequent carbon cycling in the lower euphotic zone. For example, decreased light flux during the winter months appears to prevent photosynthetic plankton from utilizing available nutrients in the lower euphotic zone, resulting in the accumulation of nutrients (upwards of 36 mmol m^{-2} nitrate, Letelier et al. 2004). However, once sufficient light becomes available to these dimly lit waters in the spring, phytoplankton biomass increases, coincident with nitrate drawdown (Letelier et al. 2004). To date, there is limited information on the contributions of major groups of photosynthetic organisms to temporal variations in primary productivity at Station ALOHA, or on how time-varying changes in the upper ocean habitat influence phytoplankton production and growth in this ecosystem.

Examination of picoplankton contributions to primary productivity has been typically conducted through the size-partitioning of productivity using a range of filter pore sizes to separate plankton biomass. In addition, studies have characterized the specific contributions of picoplankton assemblages to rates of primary production through particle size distributions (Barone et al. 2015, White et al. 2015), specific photosynthetic pigment-based labeling (Goericke & Welschmeyer 1993, Pinckney et al. 1996), and flow cytometric sorting of radiolabeled cells (Li 1994, Jardillier et al. 2010, Björkman et al. 2015, Rii et al. 2016). In the current study, we relied on combined size-fractionated measurements of ^{14}C-bicarbonate assimilation and flow cytometric sorting of ^{14}C-labeled picoplankton populations to examine vertical and temporal patterns in carbon fixation on 11 cruises to Station ALOHA spanning a 1 yr period. The resulting measurements provided quantitative information on the contributions of dominant groups of picophytoplankton to carbon fixation in this persistently oligotrophic ecosystem.

MATERIALS AND METHODS

Sample collection

Seawater was collected in 12 l polyvinylchloride bottles affixed to a rosette sampler equipped with

Table 1. Sampling dates, variability in light, mixed layer depths (mean ± SD), and depth-integrated (0–125 m) inventories of chlorophyll *a* (chl *a*), *Prochlorococcus* (PRO), *Synechococcus* (SYN), and photosynthetic picoeukaryotes (PPE) measured during this study. a Sea-Bird 911+ conductivity, temperature, and pressure sensors. Size-fractionated and group-specific rates of ^{14}C-assimilation were measured between May 2012 and May 2013 on 10 HOT program cruises (H242–H243, H245–H252) and 1 Center for Microbial Oceanography: Research and Education (C-MORE) research cruise (termed HOE-DYLAN V, or HD5) to Station ALOHA (Table 1).

In situ measurements of ^{14}C-bicarbonate assimilation

Rates of size-fractionated (>3 and 0.2–3 µm) and group-specific particulate ^{14}C-based primary production were measured at 6 discrete depths (5, 25, 45, 75, 100, and 125 m) throughout the euphotic zone. These depths were chosen to complement the ongoing, long-term HOT program measurements of ^{14}C-based primary production (Karl & Church 2014). Seawater samples from each depth were subsampled into triplicate 30 ml polycarbonate centrifuge tubes (Nalgene™) from a pre-dawn cast, inoculated under subdued light with 70 µl of NaH^{14}CO$_3$ (final activity = ~0.14 MBq ml^{-1}; MP Biomedicals 17441H), then incubated over the full photoperiod (~12–14 h) in white mesh bags affixed to a floating *in situ* array at the corresponding depths where the water was collected.

At the end of the incubation period (after sundown), each polycarbonate tube was sampled for size-fractionated and group-specific rates of ^{14}C primary productivity. Aliquots (25 µl) were subsampled from each tube and stored in 20 ml glass scintillation vials containing 500 µl of β-phenylethylamine to

determine the total activity of ^{14}C added to each sample. Next, 5 ml of each sample were preserved in cryotubes containing 30 µl of 16% (final concentration 0.24% w/v) microscopy-grade paraformaldehyde (PFA, Alfa Aesar 43368), flash-frozen in liquid nitrogen, and stored at −80°C for subsequent flow cytometric sorting. The remaining sample volume (~25 ml) was vacuum-filtered first onto a 25 mm diameter, 3 µm pore size polycarbonate membrane (Millipore Isopore™), and then the filtrate was vacuum-filtered onto a 25 mm diameter, 0.2 µm pore size polycarbonate membrane filter (GE Osmonics). After filtration, each filter was placed into a 20 ml glass scintillation vial and stored at −20°C until analyzed back at the shore-based laboratory. Upon return to shore, vials were uncapped, 1 ml of 2 M hydrochloric acid was added to each filter, and vials were vented for at least 24 h to remove remaining inorganic ^{14}C. After venting, 10 ml of Ultima Gold liquid scintillation cocktail were added to each vial, and vials were placed in a liquid scintillation counter (Packard TRI-Carb 4640) for the determination of ^{14}C activities. In this study, ^{14}C primary productivity measured on the 3 µm membrane is termed the '>3 µm' fraction, and the productivity measured on the 0.2 µm membrane (hence representing 0.2–3 µm) is referred to as the 'picophytoplankton' fraction. We refer to the sum of the >3 µm and the picophytoplankton fractions as the 'total' ^{14}C primary productivity.

Group-specific rates of ^{14}C-assimilation by *Prochlorococcus*, *Synechococcus*, and PPE were determined by measuring the amount of ^{14}C assimilated into populations sorted using the BD Influx™ (100 µm nozzle tip, 1X BioSure® sheath solution).

Calibration of the number of cells sorted was conducted at the beginning of each sorting session; a known number of fluorescent microspherical beads (1 μm, Fluoresbrite, Polysciences) were gated through the data acquisition software Spigot, sorted onto a slide, and checked for accuracy under the microscope. The '1.0 drop purity' setting in the Spigot software was used as a conservative way of ensuring accuracy of the types of cells sorted into two 6.5 ml HDPE scintillation vials with the '2 tube sort' setting. Beads were included with the samples for size reference, and 200 to 4000 beads were sorted for the determination of background levels of radioactivity (both organic ^{14}C in the seawater and ^{14}C absorbed to the beads). Picophytoplankton cells were triggered on forward scatter (FSC) and enumerated based on FSC and side scatter, chlorophyll-based red fluorescence (692 ± 20 nm), and phycoerythrin-based orange fluorescence (585 ± 20 nm) following excitation with 2 lasers, 488 nm (200 mW) and 457 nm (300 mW), through separate pinholes.

Prochlorococcus and *Synechococcus* cells were identified based on red fluorescence signals against FSC, then further gated by side scatter and orange fluorescence. PPE cells were distinguished based on high red fluorescence and low orange fluorescence in reference to FSC, and excluding *Prochlorococcus* and *Synechococcus* gates. For each picophytoplankton group, the number of cells sorted ranged from 25 000 for *Prochlorococcus*, 100 to 10 000 for *Synechococcus*, and 360 to 35 000 for PPE. Linearity between cells sorted and radioactivity was checked regularly. We were unable to sort a sufficient number of *Synechococcus* cells for detection of radioactivity at 100 m for August, October, and December 2012, and at 125 m for all months except in March 2013. After sorting, 200 μl of 2 M hydrochloric acid were added to each vial containing the cells, and vials were vented for 48 h, followed by addition of 4 ml of Ultima Gold liquid scintillation cocktail. After 1 h, the vials were placed in a liquid scintillation counter (Packard TRI-Carb 4640) for the determination of ^{14}C activities (30 min count time per sample). The resulting radioactivities were converted to average cell-specific and group-specific ^{14}C-assimilation rates based on total radioactivity added to the incubations, measured dissolved inorganic carbon concentrations (from the HOT Data Organization and Graphical System, http://hahana.soest.hawaii.edu/hot/hot-dogs), a correction for preferential assimilation of ^{12}C relative to ^{14}C (Steemann Nielsen 1952), the number of cells sorted, and the measured cell abundances (see next section).

Picophytoplankton cell abundance and biomass calculations

Seawater (2 ml) was collected into cryotubes (Corning) containing a final concentration of 0.24 % (w/v) microscopy-grade PFA. Cryotubes were stored at room temperature for 15 min in the dark, then flash-frozen in liquid nitrogen and stored at −80°C until analysis. Each picophytoplankton population was distinguished with the same fluorescence and scatter parameters described above, and cell counts were determined using the data analysis software FlowJo 10.0.7.

Flow cytometric determinations of FSC were used to estimate cell size using an empirically derived relationship between measured FSC and epifluorescence microscopy-derived estimates of cell diameters. Laboratory cultures of the picocyanobacteria *Prochlorococcus* spp. (MIT 9301) and 5 isolates of PPE from Station ALOHA and Kāneʻohe Bay, Oʻahu, Hawaiʻi (*Micromonas* spp., KB-FL13; raphidophyte, KB-FL10; *Pelagomonas* spp., AL-D101-P; chlorarachniophyte, AL-FL05; and *Chrysochromulina* spp., AL-TEMP-12), were used to determine an FSC-to-cell size relationship with flow cytometer settings identical to sorting and counting. The cells were first identified based on autofluorescence using epifluorescence microscopy on a Nikon Eclipse 90i using a chlorophyll-specific filter set (480/30 nm excitation, 600 nm emission), and digital images of the cells (magnified 1000×) were captured under bright-field illumination. Cell diameters were estimated from the imaged microscopy fields using a calibrated length tool in the image analysis software NIS Elements AR 3.22.11. FSC measurements were linearly normalized to 1 μm beads analyzed concurrently with the cultivated isolates (Table A1 in the Appendix). An empirically derived power equation (cell diameter [μm] = 0.3071×[FSC]$^{0.2857}$, R^2 = 0.99) was used to estimate the mean cell diameters of *Prochlorococcus*, *Synechococcus*, and PPE cells sorted in this study (Table A2 in the Appendix). Cell biovolume was calculated assuming a spherical shape, and carbon biomass was estimated using 2 approaches: first using the biovolume-carbon conversion factor 237 fg C μm^{-3} (Worden et al. 2004), and the second using the empirical function described by Eppley et al. (1970) and applied by Shalapyonok et al. (2001). Both of these approaches yielded comparable estimates of cell biomass; hence, for the current study, we used the biovolume-carbon conversion factor (237 fg C μm^{-3}) for subsequent estimates of photosynthetic picoplankton biomass.

Mixing, light, nutrients, and pigments

Physical and biogeochemical characteristics of the water column were obtained as part of the near-monthly HOT program core measurements at Station ALOHA (http://hahana.soest.hawaii.edu/hot/hot-dogs/). The mixed layer depth for each research cruise was defined as the depth where a 0.125 potential density offset was observed relative to the near-surface ocean waters (<5 m; Brainerd & Gregg 1995). A HyperPro radiometer (Satlantic) was used to collect daily vertical profiles of midday downwelling PAR, and coincident measurements of incident PAR were collected using a deckboard radiometer (Satlantic). Together, these measurements were used to compute the downwelling PAR attenuation coefficient (K_{PAR}). Daily-integrated PAR (400 to 700 nm) at the sea surface was measured with a LI-COR LI-1000 cosine collector and data logger. The flux of downwelling PAR at the discrete depths where productivity measurements were conducted was derived from measured K_{PAR} values and the daily-integrated incident PAR measurements. For the determination of nitrate + nitrite ($NO_3^- + NO_2^-$) in the upper 125 m, seawater samples collected at each depth were analyzed in triplicate following a high-sensitivity chemiluminescent method (Garside 1982, Dore & Karl 1996). HOT program measurements of high performance liquid chromatography (HPLC)-derived chl *a* were obtained following the protocols of Bidigare et al. (2005).

Data analyses

For statistical analyses, data sets were tested for normality using the Shapiro-Wilk test (Royston 1982) and quantile–quantile plots, and those that rejected the null hypothesis (p > 0.05) were $\log_{10}$-transformed. Comparisons between 2 sets of normally distributed samples were conducted with Welch's *t*-test (Welch 1951). When $\log_{10}$ transformation was not successful in attaining normality, non-parametric methods (Kruskal-Wallis test, Hollander & Wolfe 1973) were used to test for significant differences between data sets.

The euphotic zone at Station ALOHA typically extends below the penetration depth of the 1% surface PAR, which oscillates between ~85 and 125 m. For this study, examined parameters were depth-integrated to 125 m, capturing the region of the ocean where the majority of the photosynthetic biomass resides and rates of productivity are greatest (e.g. rates of ^{14}C primary production below 125 m contribute <3% to the 0–175 m integrated production, http://hahana.soest.hawaii.edu/hot/hot-dogs/). In addition, we examined temporal dynamics of picophytoplankton productivity in the 'upper' (0–45 m) and the 'lower' (75–125 m) regions of the euphotic zone. The upper region represented the persistently low-nutrient, high-light conditions within the mixed layer where rates of ^{14}C-bicarbonate assimilation have been shown to be light-saturated (Church et al. 2004, Li et al. 2011, Viviani et al. 2015). In contrast, the lower euphotic zone represented the nutrient-enriched, but low-light portion of the upper pycnocline where rates of plankton production are light-limited (Letelier et al. 2004, Li et al. 2011).

RESULTS

Variability in upper ocean biogeochemistry

Biogeochemical conditions in the upper ocean during our study period (May 2012 to May 2013) were consistent with the long-term HOT program climatology at Station ALOHA (Fig. 1). The depth of the mixed layer ranged from ~36 to 60 m from the late spring through fall, deepening to ~77 to 126 m between December to April (Table 1). The flux of PAR at 25 m (within the upper euphotic zone) was greatest from April to August, with lowest fluxes (~3-fold lower) in December (Table 1, Fig. 1A). Downwelling PAR flux at 100 m (within the lower euphotic zone) tended to be greatest between April and June and declined steadily thereafter (Fig. 1B). The depth of the 1% surface PAR isopleth was relatively stable during our study period, shoaling to 106–110 m between August and February and deepening to 115–118 m between March and June (Table 1). Inventories of $NO_3^- + NO_2^-$ in the well-lit regions of the upper euphotic zone were persistently low and demonstrated no apparent seasonality (1-way ANOVA, p = 0.97, Fig. 1C). In contrast, $NO_3^- + NO_2^-$ inventories in the lower euphotic zone were more temporally variable, with elevated concentrations in November, December, and February (pairwise Tukey and Kramer, p < 0.05, Fig. 1D). Inventories of HOT program chl *a* in the upper euphotic zone were temporally variable (Kruskal-Wallis, p < 0.0001), with generally elevated concentrations from November to February compared to the other months (pairwise Tukey and Kramer, p < 0.05, Fig. 1E). Chl *a* inventories in the lower euphotic zone were not significantly different on monthly time scales (ANOVA, p = 0.18, Fig. 1F).
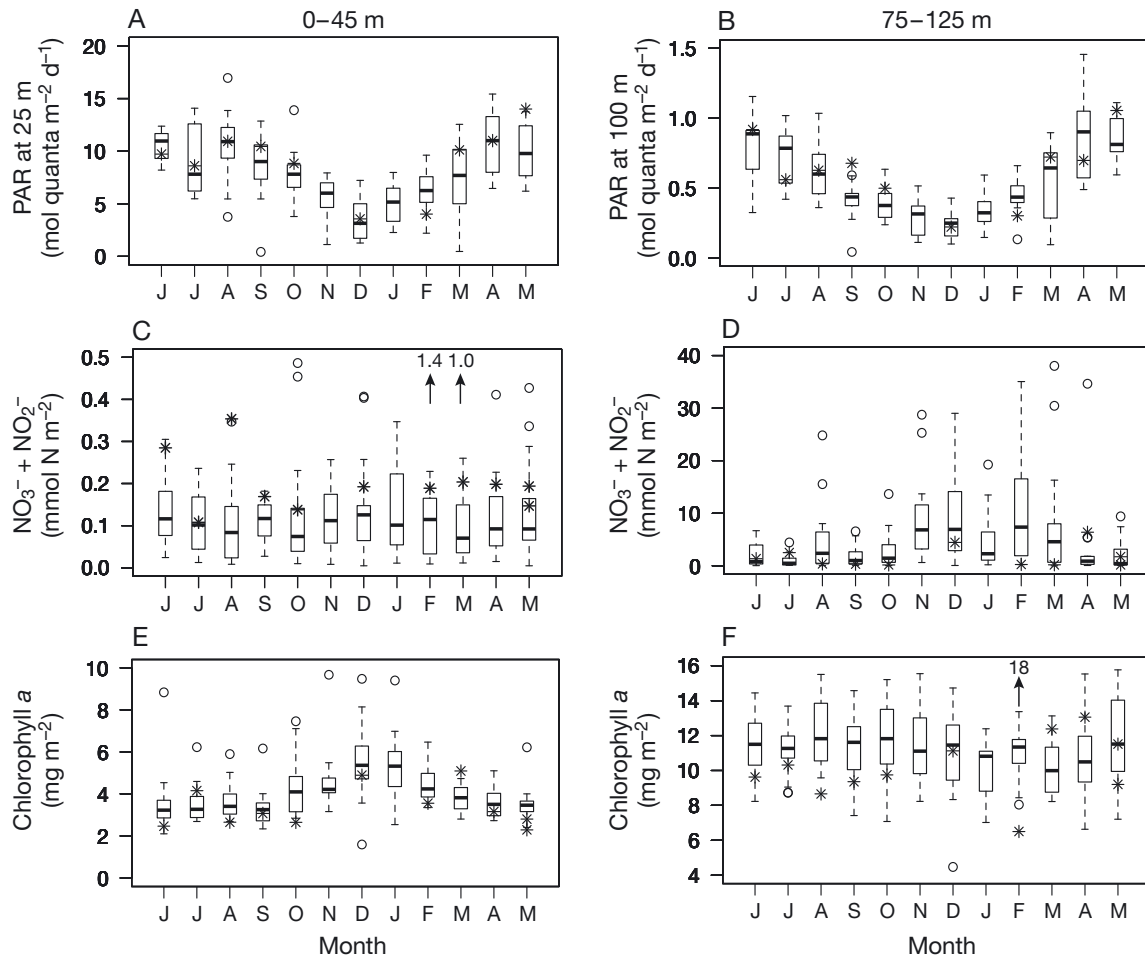

Fig. 1. Monthly-binned biogeochemical properties at Station ALOHA: daily PAR flux (1998–2013) at (A) 25 m and (B) 100 m; NO_3^- + NO_2^- (1989–2013) in the (C) upper (0–45 m) and (D) lower (75–125 m) euphotic zone; and inventories of chl *a* (1989–2013) in the (E) upper and (F) lower euphotic zone. Note scale differences between the panels. Measurements conducted as part of the current study (May 2012 to May 2013) are symbolized as stars ($*$). For each boxplot: dark horizontal line indicates the median, the box boundaries span the 1st (25th percentile) to the 3rd quartile (75th percentile), and the whiskers extend to the maximum and minimum (boundary $\pm$ 1.5× interquartile range) of the selected measurements. Outlier observations, considered to be beyond the maximum and minimum limits of the observations, are depicted as open circles, and observations falling outside the scale of the plot region are indicated by arrows and measurement values

Size partitioning of ^{14}C primary productivity

In general, picophytoplankton contributions to depth-integrated (0–125 m) rates of ^{14}C assimilation were ~3-fold greater (ranging from 8.8 to 26.4 mmol C m^{-2} d^{-1}) than contributions by phytoplankton >3 µm (ranging from 2.5 to 8.8 mmol C m^{-2} d^{-1}; Table 2). Picophytoplankton comprised ~68 to 83% of total depth-integrated (0–125 m) rates of productivity, with their contributions to total ^{14}C primary productivity somewhat greater in the lower (76–90%) than in the upper (65–78%) euphotic zone (Welch's *t*-test, p < 0.005; Table 2). Approximately half (41–59%) of the 0–125 m picophytoplankton ^{14}C-based productivity occurred in the upper euphotic zone, while greater than half (55–75%) of the 0–125 m >3 µm

production occurred in the upper euphotic zone (Fig. 2). In the upper euphotic zone, rates of ^{14}C-based picophytoplankton productivity were greatest between May and July 2012, and between March and May 2013 (Table 2); in the lower euphotic zone, depth-integrated rates of picophytoplankton primary production were lowest in December 2012 (~1.5 mmol C m^{-2} d^{-1}) and increased ~5-fold in March 2013 (Table 2).

Variability in picophytoplankton cell abundances and biomass

Picophytoplankton cell abundances measured during our study were consistent with the historical HOT

Table 2. Depth-integrated rates of size-fractionated ^{14}C primary production in the upper, lower, and total euphotic zone. Shown are mean ± SD of triplicate bottles (in mmol C m^{-2} d^{-1}); values in parentheses are percentages ± SD of each size fraction relative to the total (>0.2 μm) ^{14}C primary production. Cruises as in Table 1, except for H243 for which samples were compromised

program measurements of these organisms. Cell abundances ranged from 36.8 × 10^9 to 336.3 × 10^9 cells m^{-3}, below detection to 5.4 × 10^9 cells m^{-3}, and 0.5 × 10^9 to 2.3 × 10^9 cells m^{-3} for *Prochlorococcus*, *Synechococcus*, and PPE, respectively (Fig. 3A–C). *Prochlorococcus* cell abundances in the upper 125 m were relatively stable during our sampling period, demonstrating ~1.5-fold increases in April and May 2013 (Table 1). Similarly, PPE cell abundances were also relatively stable, varying ~2-fold over the sampling period, with lowest abundances in October 2012 (Table 1). In contrast, *Synechococcus* cell abundances were more dynamic, varying ~3- to 5-fold, with largest increases in abundance observed between February and April 2013.

Picophytoplankton mean cell diameters were estimated from flow cytometric measurements of FSC using an empirical equation derived using cultures of *Prochlorococcus* and several PPE (Table A1). For this study, estimated picophytoplankton cell sizes in the 0–125 m were 0.4 ± 0.3, 0.7 ± 0.4, and 1.5 ± 1.1 μm for *Prochlorococcus*, *Synechococcus*, and PPE, respectively (Table A2). The resulting average per cell carbon content ranged from 9 to 12 fg C cell^{-1} for *Prochlorococcus*, 43 to 50 fg C cell^{-1} for *Synechococcus*, and 445 to 453 fg C cell^{-1} for PPE (Table A2). While both *Prochlorococcus* and *Synechococcus* mean cell diameters increased ~20% from the upper to the lower regions of the euphotic zone, PPE mean cell diameters decreased ~8% (Table A2).

Estimations of carbon biomass derived from measured cell abundances and biovolumes revealed that *Prochlorococcus*, *Synechococcus*, and PPE comprised 61–78, 2–8, and 21–36%, respectively, of the summed picophytoplankton biomass in the euphotic zone (0–125 m; Table 3). The biomass of *Prochlorococcus* and PPE in the euphotic zone were relatively stable in time, varying ~2-fold over the study period (ranging from 9.1 to 20.9 mmol C m^{-2} and 3.1 to 7.7 mmol C m^{-2}, respectively) with highest biomass observed during the summer and spring months (Table 3). In contrast, *Synechococcus* biomass varied ~13-fold (ranging from 0.2 to 2.6 mmol C m^{-2}), with biomass greatest in February, March, and April of 2013 (Table 3).

Temporal variability of *Prochlorococcus*, *Synechococcus*, and PPE revealed differing dynamics in the upper and the lower regions of the euphotic zone. Depth-integrated biomass of each picophytoplankton group in the upper euphotic zone was similar to its biomass in the lower euphotic zone; however, variability in *Prochlorococcus* biomass in the lower euphotic zone was greater than in the upper euphotic zone, while PPE biomass exhibited greater variability in the upper compared to the lower euphotic zone (Fig. 3D,F). In the upper euphotic zone, seasonal increases during the spring and summer months were apparent in biomass of *Prochlorococcus* and PPE, with the largest increases in biomass observed from fall months to spring (~4-fold increase from September 2012 to March 2013 for *Prochlorococcus* and 4-fold increase from September 2012 to May 2013 for PPE; Fig. 4A). *Synechococcus* biomass was also elevated in spring, demonstrating a 16-fold increase from September 2012 to March 2013 in the upper euphotic zone (Fig. 4A). In the lower euphotic zone, PPE biomass varied ~2-fold, with peak inventories in the spring and summer months (Fig. 4B). Similarly, *Synechococcus* biomass increased 8-fold in March 2013 compared to other months. *Prochlorococcus* biomass fluctuated throughout the year, with 2-fold higher inventories in June, August, and December 2012 and March 2013 compared to other months (Fig. 4B).
Fig. 2. Rates of ^{14}C-primary production by (A) pico- (0.2–3 µm) and (B) larger (>3 µm) phytoplankton between May 2012 and May 2013. Black circles indicate sampling depths, and values are means of triplicate samples

Group- and cell-specific rates of ^{14}C assimilation, and biomass-normalized production

Prochlorococcus, *Synechococcus*, and PPE comprised 39 ± 20, 1.6 ± 1.7, and 11 ± 6% of the total (>0.2 µm) ^{14}C primary productivity, respectively. *Prochlorococcus* accounted for 63 to 86% of the 0–125 m depth-integrated rates of sorted picophytoplankton ^{14}C-production, with *Synechococcus* and PPE accounting for the remaining 1 to 8% and 12 to 36%, respectively (Table 3). Relative contributions by *Prochlorococcus* to picophytoplankton production demonstrated modest increases with depth, accounting for 81 ± 5% of the summed picophytoplankton productivity in the lower euphotic zone compared to 72 ± 9% in the upper euphotic zone (Welch's *t*-test, p < 0.05; Fig. 5). In contrast, relative contributions by PPE

tended to be greater in the upper euphotic zone relative to the lower euphotic zone (25 ± 9% versus 17 ± 6%; Welch's *t*-test, p < 0.05; Fig. 5). Group-specific rates of ^{14}C-productivity by *Prochlorococcus* varied ~5-fold during our study period, with elevated rates between June and August 2012 and between March and May 2013, and lowest rates in October 2012 (Table 3, Fig. 5). Group-specific rates of production by *Synechococcus* varied as much as ~30-fold during this study, with the highest rates in June to August 2012 and March to May 2013, and lowest in September 2012. These large increases in group-specific rates of production by *Prochlorococcus* and *Synechococcus* in summer 2012 and spring 2013 also coincided with periods of elevated production in the picophytoplankton filter fraction (Fig. 2). For PPE, group-specific rates of ^{14}C-productivity varied
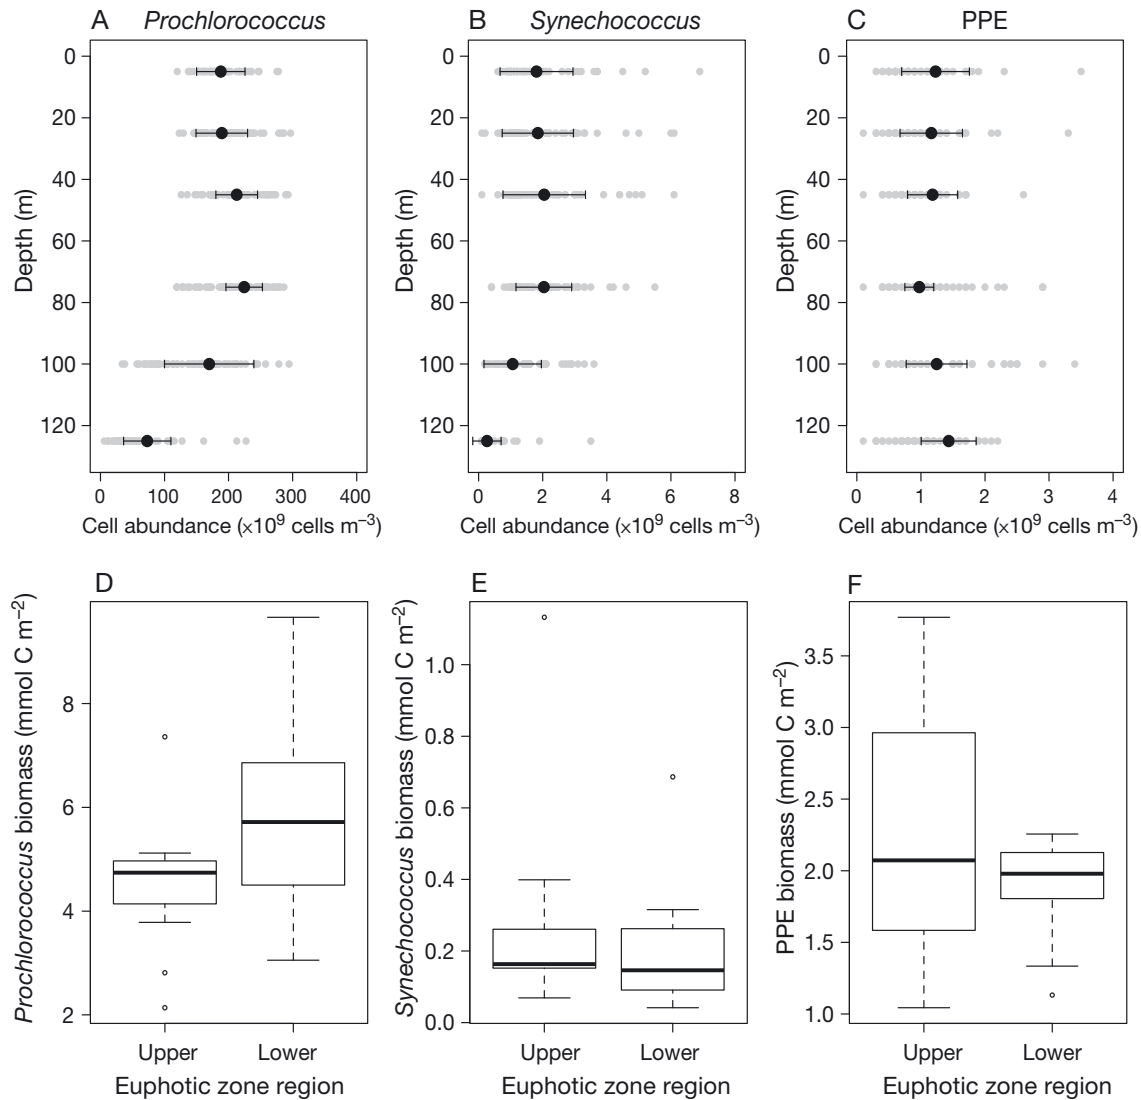

Fig. 3. (A) *Prochlorococcus*, (B) *Synechococcus*, and (C) photosynthetic picoeukaryotes (PPE) cell abundances at Station ALOHA between 2006 and 2013 (grey circles), with overlay of black circles (mean) and error bars (standard deviations) for measurements obtained during the current study period (May 2012 to May 2013). Note scale differences between the panels. Depth-integrated estimated carbon biomass of (D) *Prochlorococcus*, (E) *Synechococcus*, and (F) PPE in the upper (0–45 m) and lower (75–125 m) euphotic zone (from this study) are shown, with the same boxplot boundaries as those described in Fig. 1

~4-fold in time, with lowest rates in December 2012 and elevated rates in June to July 2012 and February to May 2013 (Table 3). Combined, the sum of sorted picophytoplankton productivity accounted for 52% (on average) of the total ^{14}C primary productivity (sum of the filter size fractions) and 70 ± 32% of the picophytoplankton filter-based (0.2–3 µm) primary productivity.

Normalizing the sort-based rates of productivity to cell abundances highlighted large differences in cell-specific production by these groups of picophytoplankton. Cell-specific rates of ^{14}C-production by *Prochlorococcus* were generally low (averaging 0.4 ±

0.2 fmol C cell^{-1} d^{-1}), with *Synechococcus* exhibiting somewhat higher rates (averaging 1.6 ± 1.2 fmol C cell^{-1} d^{-1}). In contrast, PPE demonstrated rates (averaging 16 ± 12 fmol C cell^{-1} d^{-1}) that were 25- to 95-fold greater than those by *Prochlorococcus* (Fig. 6). Throughout this study period, depth-integrated (0–125 m) *Prochlorococcus* and *Synechococcus* cell-specific rates of ^{14}C-assimilation appeared temporally dynamic, with rates lowest between August and October 2012 and increasing between February and March 2013, with the highest rates measured in March 2013 (Fig. 6A,C). Cell-specific rates of production by PPE tended to be less variable,

Table 3. Depth-integrated (0–125 m) rates of picophytoplankton (PRO: *Prochlorococcus*, SYN: *Synechococcus*, PPE: photosyn-thetic picoeukaryotes) biomass, group-specific carbon fixation, and biomass-normalized production. Biomass was calculated using the biomass conversion factor 237 fg C μm^{-3} from Worden et al. (2004) applied to biovolumes estimated using mean cell diameters and assuming a spherical shape. Values in parentheses are the percentage contribution of each group relative to the summed contributions of PRO, SYN, and PPE. Cruises as in Table 1

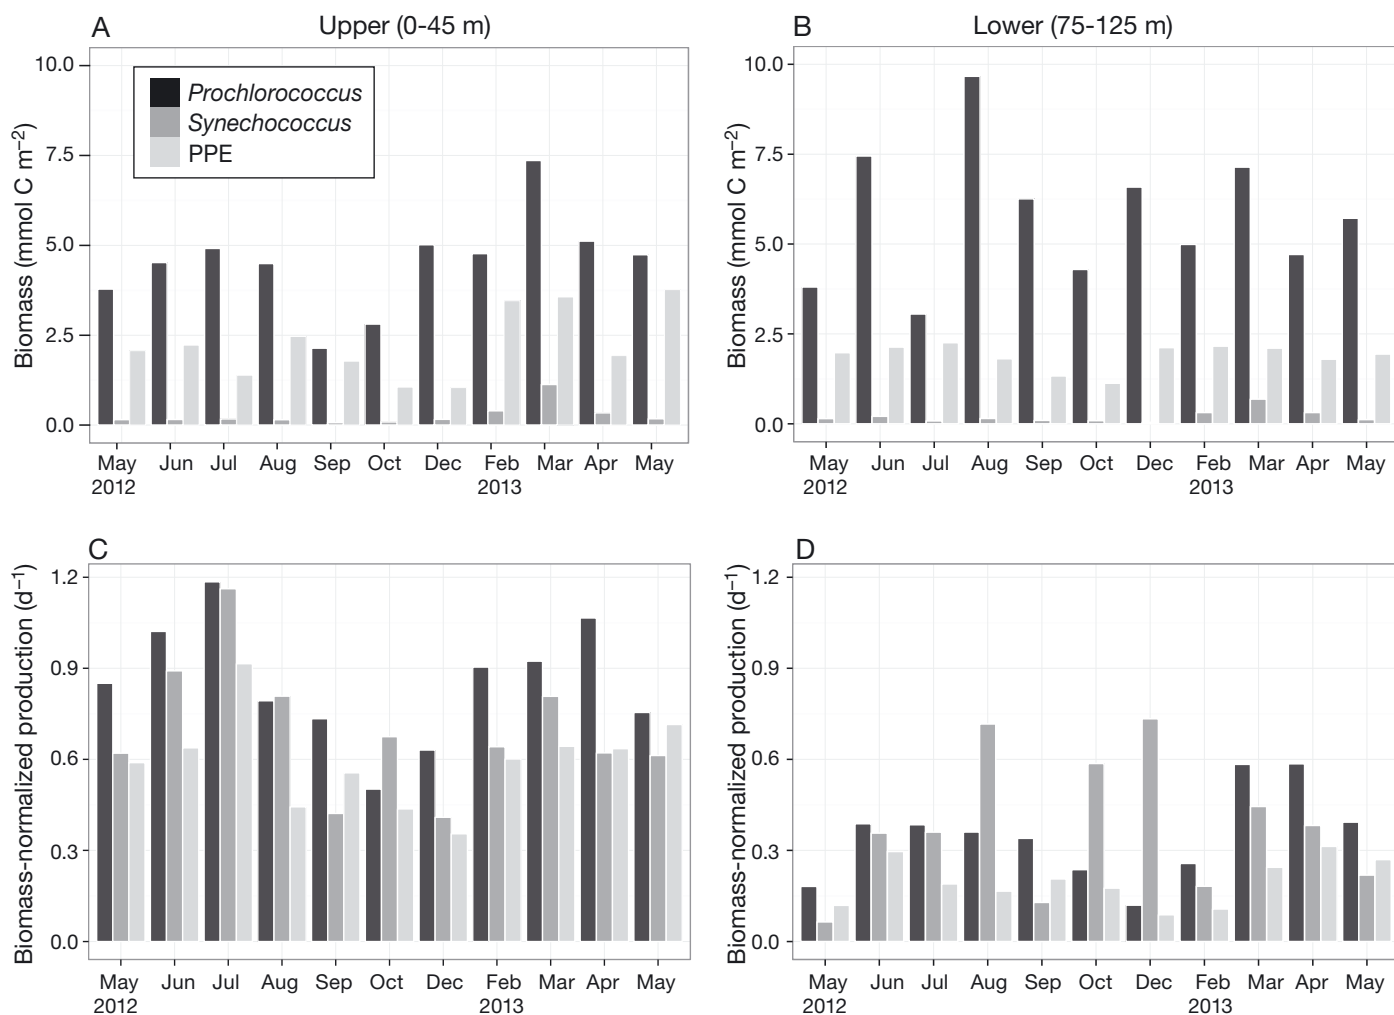

Fig. 4. Temporal variability in (A, B) derived biomass and (C, D) biomass-normalized production by *Prochlorococcus* (dark grey bars), *Synechococcus* (medium grey bars), and photosynthetic picoeukaryotes (PPE, light grey bars) between May 2012 and May 2013
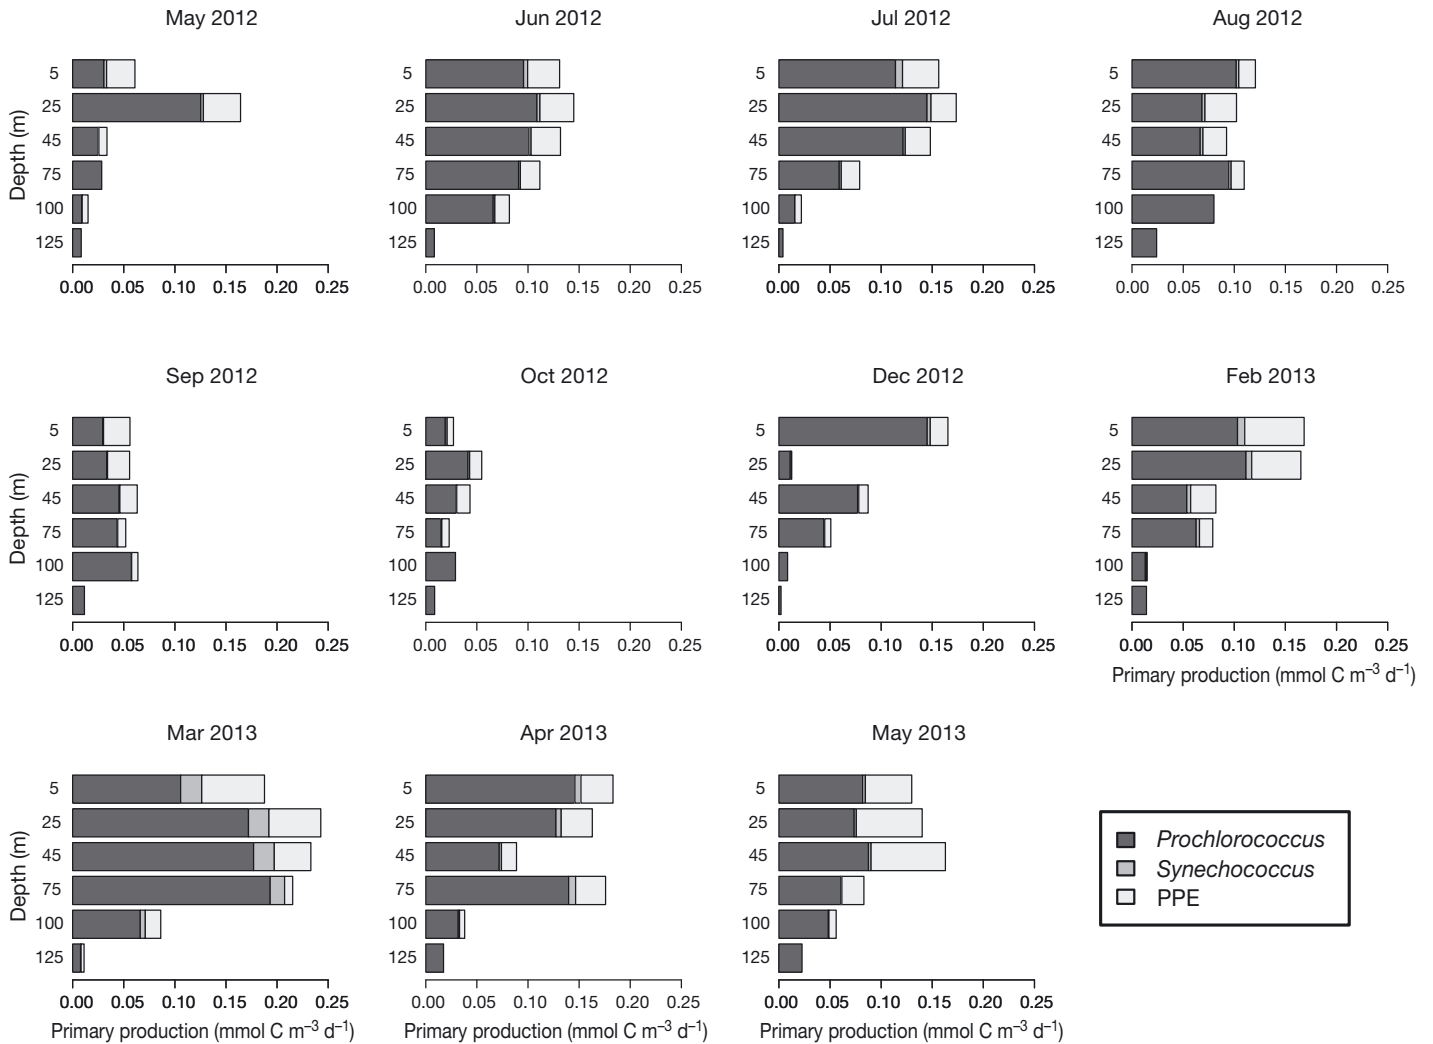

Fig. 5. Vertical profiles of group-specific rates of ^{14}C-based primary productivity by *Prochlorococcus* (dark grey bars), *Synechococcus* (medium grey bars), and photosynthetic picoeukaryotes (PPE, light grey bars) between May 2012 and May 2013. Due to insufficient number of cells sorted, *Synechococcus* contributions were not measured at 100 m in August, October, and December 2012, and not measured at 125 m in all months sampled except March 2013

with the greatest changes in cell-specific productivity occurring in the upper euphotic zone and with the highest rates observed in May 2013 (Fig. 6E). PPE cell-specific rates were significantly greater (3.5-fold on average) in the well-lit waters (<45 m) than in the lower euphotic zone (Kruskal-Wallis, p < 0.005, Fig. 6F). In comparison, cell-specific rates of ^{14}C-primary productivity for both *Prochlorococcus* and *Synechococcus* in the upper euphotic zone were ~1.7-fold greater than rates in the lower euphotic zone (Kruskal-Wallis, p < 0.005, Fig. 6B, D).

Estimates of biomass-normalized production in the euphotic zone (0–125 m) for *Prochlorococcus*, *Synechococcus*, and PPE ranged from 0.3 to 0.9, 0.3 to 0.8, and 0.2 to 0.6 d^{-1}, respectively (Table 3). Normalized rates of production by *Prochlorococcus* and *Syne-*

chococcus were typically greater than PPE, with *Prochlorococcus* and *Synechococcus* in the upper euphotic zone averaging 0.9 ± 0.2 and 0.7 ± 0.2 d^{-1}, respectively, while PPE averaged 0.6 ± 0.2 d^{-1} (Fig. 4C). In the lower euphotic zone, normalized rates of production were lower, averaging 0.3 ± 0.1, 0.4 ± 0.2, and 0.2 ± 0.1 d^{-1} for *Prochlorococcus*, *Synechococcus*, and PPE, respectively (Fig. 4D). For all picophytoplankton, the highest biomass-normalized rates of production in the upper euphotic zone occurred in July 2012, where rates were ~3-fold greater than in October to December 2012 (Fig. 4C). In the lower euphotic zone, rates by *Prochlorococcus* and PPE varied 5- and 4-fold, respectively, over the course of the study, with rates greatest in March and April 2013 (Fig. 4D).

DISCUSSION

We examined the vertical and temporal variability in rates of picophytoplankton ^{14}C-based primary productivity at Station ALOHA in the oligotrophic NPSG based on filter size fractionation and flow cytometric sorting of radiolabeled cell populations. Picophytoplankton dominated rates of ^{14}C-based primary production, accounting for >70% of the total productivity throughout the year. This finding is consistent with past studies that have observed the importance of picophytoplankton to carbon cycling in both oligotrophic and nutrient-rich waters (e.g. Li 1994, Agawin et al. 2000, Marañón et al. 2001, Li et al. 2011, Buitenhuis et al. 2012, Rii et al. 2016). In the current study, greatest rates of both filter-based and sorted [14]C-

based primary productivity were measured in the spring and summer months in the upper euphotic zone, while peak productivity in the lower euphotic zone corresponded with periods when the flux of light to the lower euphotic zone was greatest (March to April 2013). Moreover, the observed depth variability in the size partitioning of productivity indicated that while picophytoplankton contributed to primary production throughout the euphotic zone, larger (>3 µm) phytoplankton contributions were greater in the upper euphotic zone compared to in deeper waters. These findings suggest that in this ecosystem, picophytoplankton may be better adapted to low-light regions of the euphotic zone than larger phytoplankton.

Consistent with the numerical dominance and estimated carbon biomass of *Prochlorococcus*, these

organisms contributed >60% to the total sorted pico-phytoplankton productivity (equaling ~39% of total >0.2 μm filter-based productivity), which agrees with previously reported measurements at Station ALOHA (Björkman et al. 2015). In contrast to *Prochlorococcus*, PPE cell abundances were orders of magnitude lower; however, PPE contributed up to 36% to sorted picophytoplankton production and biomass (equivalent to ~11% to total filter-based productivity). These findings agree with the disproportionately high contributions of PPE (compared to cell abundance) to picophytoplankton production in the Atlantic and South Pacific Oceans (Li 1994, Jardillier et al. 2010, Rii et al. 2016), a finding we attribute to their larger cell size. Moreover, group- and cell-specific rates of primary productivity by PPE were greater in the upper 45 m, suggesting that PPE may be adapted to rapid growth in well-lit regions of the euphotic zone. Our findings are supported by previous studies demonstrating positive correlations between PPE growth and irradiance (Bec et al. 2005), as well as the various photophysiological strategies of PPE to optimize growth in high-light environments, including synthesis and accumulation of photoprotective carotenoids and rapid modification of intracellular chl *a* concentration (Dimier et al. 2009, Brunet et al. 2011). Such photophysiological adaptations may provide PPE with competitive advantages over some cyanobacteria or larger phytoplankton in the well-lit upper ocean (Ferris & Christian 1991, Dimier et al. 2009).

Our measurements allowed us to examine temporal variability in group-specific picophytoplankton production and estimated biomass over a 1 yr period. We observed that while PPE rates of production varied ~4-fold throughout the year with highest rates in May 2013, biomass varied ~2.5-fold, indicating that while PPE may be responding to conditions favoring production, removal processes including grazing, cell lysis, or export are tightly coupled to production, keeping biomass relatively stable. Similar dynamics were observed for *Prochlorococcus*, whose rates of production varied ~5-fold (highest rates in July 2012 and March 2013), while biomass varied ~1.5-fold, resulting in relatively stable rates of normalized production throughout the year. In contrast, *Synechococcus* appeared more temporally dynamic, with group-specific rates of ^{14}C-primary production increasing ~30-fold, with highest rates in summer 2012 and spring 2013, while biomass of these picophytoplankton increased ~13-fold in spring 2013. The resulting rates of biomass-normalized production for these groups ranged from 0.3 to 0.9 d^{-1} for *Prochlorococcus*, 0.3 to 0.8 d^{-1} for *Synechococcus*, and 0.2 to

0.6 d^{-1} for PPE. These rates are similar to previously published estimates on growth rates of these picoplankton. For example, laboratory studies with *Prochlorococcus* isolates indicated maximal growth rates of ~0.6 d^{-1} (Liu et al. 1995, Moore et al. 1995, Claustre et al. 2002). In a study in the subtropical North Pacific, Ribalet et al. (2015) estimated *Prochlorococcus* growth rates ranging from 0.2 to 0.9 d^{-1} based on diel changes in cell size and abundances. Measurements from the California coast reported growth rates estimated from dilution experiments to be ~0.7 d^{-1} for *Synechococcus* and ~1 d^{-1} for PPE (Worden et al. 2004).

Our findings highlight the important trophodynamic role of picophytoplankton in the oligotrophic ocean, with cell loss processes tightly coupled to cell growth. Our rates of production normalized to biomass were generally greater in the upper euphotic zone, presumably reflecting greater light availability. However, picophytoplankton biomass was comparable between the 2 regions of the euphotic zone, suggesting more rapid turnover of biomass in the upper euphotic zone. Such results are consistent with a number of studies quantifying cell loss processes in warm, well-lit regions of oligotrophic oceans that have found tight coupling between picoplankton growth and removal (Cochlan et al. 1993, Agusti et al. 1998, Liu et al. 1995, Worden et al. 2004). Moreover, our findings suggest that the degree of coupling between growth and removal differs amongst the picophytoplankton, with *Prochlorococcus* and PPE production apparently tightly coupled to removal processes, while the controls on *Synechococcus* production appear more variable. Thus, these results support the view that picophytoplankton growth can be critical to the transfer of organic material to higher trophic levels (Reckermann & Veldhuis 1997, Brown et al. 1999, Worden et al. 2004).

Collectively, our measurements of production and estimated biomass suggest that various groups of picophytoplankton are growing rapidly in this ecosystem, despite persistently limited supply of nutrients to the upper ocean. While short-lived physical events can vertically transport nitrate at near-monthly frequencies, such events appear largely restricted to the lower euphotic zone (Johnson et al. 2010). We suspect that the observed increase in net picophytoplankton growth in spring 2013 (largely due to *Prochlorococcus* and *Synechococcus*) may be a result of deepening isolumes during the spring, alleviating light-limited phytoplankton production in the lower euphotic zone and resulting in rapid consumption of nutrients (Letelier et al. 2004). Although

many of the dominant ecotypes of *Prochlorococcus* appear incapable of growth on nitrate (Moore et al. 2002, Rocap et al. 2003), various studies have demonstrated the capacity for nitrate assimilation by selected ecotypes of *Prochlorococcus* (Casey et al. 2007, Martiny et al. 2009, Treibergs et al. 2014, Berube et al. 2015, 2016). In addition, the period of elevated *Synechococcus* production and biomass during the spring coincided with increased penetration of PAR and lower than average concentrations of nitrate in the lower euphotic zone, presumably reflecting seasonal drawdown of nutrients during production of new biomass. These results agree with past reports of *Synechococcus* responding significantly to seasonal elevations in light (DuRand et al. 2001) and nanomolar changes in nitrate concentration (Glover et al. 1988, 2007). Furthermore, our results suggest that while *Synechococcus* growth in the lower euphotic zone was responsive to variations in light and nutrients, changes in cell biomass were proportionally lower, indicating that rates of removal must vary vertically and temporally. Hence, despite their small size, picocyanobacteria may play a more significant role in transferring new nitrogen into the oceanic food web at Station ALOHA than previously estimated, thereby contributing to new production and export.

The works by Fawcett et al. (2011, 2014) and Painter et al. (2014), all conducted in the subtropical North Atlantic, provide evidence that PPE derive a significant fraction of their cellular nitrogen demand via assimilation of nitrate. However, it is not clear how applicable these results are to plankton nutritional dynamics at Station ALOHA in the subtropical North Pacific. There are significantly different dynamics with respect to nutrient supply in the North Atlantic compared to the North Pacific; for example, the highly seasonal convective mixing in the North Atlantic introduces a source of nitrate to the upper ocean, which supports a spring bloom-like productivity dynamic (Sieracki et al. 1993, Siegel et al. 2002). At Station ALOHA, the weak to moderate seasonal mixing dynamic results in an upper ocean persistently depleted in nitrate, and productivity peaks in the summer when the ocean is most stratified (Karl & Church 2014). Moreover, while nitrate appears to be a major source of new nitrogen to the upper ocean in the subtropical North Atlantic, in the subtropical North Pacific, approximately half of the new nitrogen appears to derive from nitrogen fixation (Karl et al. 1997, Church et al. 2009, Böttjer et al. 2016). In our study, we found that PPE were most active in the upper 45 m of the euphotic zone, a region that, even

with seasonal fluctuations of the mixed layer, rarely penetrates the nutricline. Therefore, even during winter mixing, the supply of nutrients to the upper euphotic zone remains very low, suggesting the PPE at Station ALOHA may be more reliant on recycled nutrient sources, facilitated in part by various forms of mixotrophic physiologies (Caron 2000, Zubkov & Tarran 2008).

We calculated equivalent spherical diameters for *Prochlorococcus*, *Synechococcus*, and PPE based on flow cytometrically derived FSC. The resulting cell diameters (0.4 ± 0.3, 0.7 ± 0.4, and 1.5 ± 1.1 μm for *Prochlorococcus*, *Synechococcus*, and PPE, respectively) tended to be lower than those reported in past studies (e.g. Bertilsson et al. 2003, Worden et al. 2004). Furthermore, use of a carbon conversion factor (237 fg C μm^{-3}, Worden et al. 2004) or application of an empirical function based on cell size (Eppley et al. 1970) yielded cellular carbon quotas somewhat lower than previously published estimates. For example, in a study in the Sargasso Sea, Casey et al. (2013) derived an empirical relationship between cellular carbon and FSC, yielding cellular carbon quotas for *Prochlorococcus* that ranged between 28 and 190 fg C cell^{-1}. Heldal et al. (2003) examined the elemental composition of single cells using X-ray microanalysis and estimated cell carbon quotas for *Prochlorococcus* between 17 and 34 fg C cell^{-1}, which were similar to those derived by Claustre et al. (2002) based on *Prochlorococcus* optical properties, and to carbon quotas of 15 to 65 fg C cell^{-1} estimated by Shalapyonok et al. (2001). Based on these previous reports, we suspect our estimates of cell sizes may be biased low; however, given that we used the same approach throughout our time series, the resulting patterns provide insight into temporal dynamics in the coupling between productivity and accumulation of biomass.

One puzzling observation from the current study was the disagreement between the filter-based and the cell sort-based estimates of ^{14}C productivity. The sum of ^{14}C primary productivity in sorted cells accounted for 70 ± 32% of the picophytoplankton filter size fraction, indicating that not all of the picophytoplankton ^{14}C primary productivity captured on filters was accounted for through cell sorting of the 3 picophytoplankton groups. These discrepancies between the filter-based and sorted picophytoplankton productivity may be due to a number of factors, including underrepresentation of less abundant, but active, phytoplankton. It is likely that the filter-based estimates of production included larger (>3 μm) cells that were not quantitatively sampled by our flow

sorting method. Temporal variability associated with the proportion of the sum of sorted productivity to the filter-based picophytoplankton productivity indicated that the proportions were greatest (74–89%) between the winter and spring months (December to May). Such results suggest a greater abundance of larger organisms during summer and fall, which may have been caught on the filter but not in our sorts. These larger organisms may be associated with the annual summertime blooms of diatom–diazotroph assemblages that occur at Station ALOHA during periods of stratification (Dore et al. 2008). In addition, there may have been loss of ^{14}C-label following PFA preservation of sorted cells (Silver & Davoll 1978). Finally, we did not account for potential contributions to ^{14}C assimilation by picoplankton with low or no pigmentation that would not be quantitatively captured by the flow sorting methodologies but could contribute to filter-based estimates of production. In a study in the North Atlantic, Jardillier et al. (2010) sorted ^{14}C-labeled nucleic acid-stained PPE (inclusive of both pigmented and non-pigmented cells) and found rates of production nearly equivalent to filter-based measurements. Thus, it is possible that measuring group-specific rates of ^{14}C assimilation by both pigmented and non- or low-pigmented cells (including mixotrophic or heterotrophic PPE, and particulate detritus) would have minimized the discrepancy between the ^{14}C assimilated by the sum of sorted cells and that caught on the picophytoplankton filter size fraction.

In summary, our examination of size-fractionated, group-, and cell-specific rates of carbon fixation and estimated picophytoplankton biomass over a period of 1 yr at Station ALOHA revealed large variations in picophytoplankton production both vertically through the euphotic zone and over time. Collectively with measurements of cell abundance and derived biomass, these results highlight that time-resolved sampling of group-specific productivity and estimated biomass yields important new information on vertical and temporal patterns in the coupling between productivity and removal processes, providing further insights into the role of picophytoplankton in oceanic carbon cycling.

APPENDIX

Table A1. Cultivated isolates used to determine empirical relationships with the forward scatter (FSC) signal of the flow cytometer. Cell diameters were estimated using epifluorescence microscopy. FSC was linearly normalized to the 1 µm beads run concurrently with the phytoplankton isolates. Values are mean ± SD

Culture and environmental isolates	Estimated diameter (µm)	FSC
Prochlorococcus spp. (MIT 9301)	0.5 ± 0.1	5.2 ± 2.1
Micromonas sp. (KB-FL13)	1.5 ± 0.2	389 ± 115
Raphidophyte (KB-FL10)	2.2 ± 0.2	1237 ± 282
Pelagomonas spp. (AL-DI01-P)	2.5 ± 0.5	2085 ± 833
Chlorarachniophyte (AL-FL05)	2.9 ± 0.4	2220 ± 121
Chrysochromulina sp. (AL-TEMP-12)	3.2 ± 0.1	2199 ± 99
Derived equation	Cell diameter (µm) = $0.3071 \times (FSC)^{0.2857}$	
R^2	0.99	

Table A2. Mean ± SD of cell diameter (µm), cell volume (µm³), and cell carbon biomass (fg C cell⁻¹) of *Prochlorococcus* (PRO), *Synechococcus* (SYN), and photosynthetic picoeukaryotes (PPE). For cell diameters, means were obtained by averaging across samples taken throughout the year and across designated depths, and SDs were calculated using the %CV of the forward scatter signal measured with the FlowJo software. For the other measurements, means and SDs were obtained by averaging across all samples

	Diameter at 0–125 m	Diameter at 0–45 m	Diameter at 75–125 m	Cell spherical volume	Cell C biomass[a]	Cell C biomass[b]
PRO	0.4 ± 0.3	0.4 ± 0.2	0.4 ± 0.3	0.04 ± 0.03	9 ± 8	12 ± 9
SYN	0.7 ± 0.4	0.6 ± 0.4	0.7 ± 0.4	0.18 ± 0.11	43 ± 26	50 ± 29
PPE	1.5 ± 1.1	1.6 ± 1.1	1.5 ± 1.1	1.9 ± 0.5	445 ± 108	453 ± 104

[a]Using carbon conversion factor 237 fg C µm⁻³ (Worden et al. 2004)
[b]Using equation (log C [pg cell⁻¹] = 0.94 × log volume [µm³] − 0.6) (Eppley et al. 1970)
