

Diatom activity within soft sediments: behavioural and physiological processes

Maria A. Saburova*, Igor G. Polikarpov

A. O. Kovalevsky Institute of Biology of the Southern Seas, Prospekt Nakhimova 2, Sevastopol 99011, Ukraine

ABSTRACT: An investigation of vertical distribution, rhythms of vertical migration and division of epipelagic free-living diatom algae was carried out at different sediment depths on intertidal sandflat in the Chernaya River Estuary (Kandalaksha Gulf, White Sea, Russia) during the summers of 1994–2001. The depth of penetration of viable microalgae cells in the sediment did not exceed 4.2 cm in the areas with clay sublayers, where zones with high negative Eh values were located closer to the surface. Diatom habitats in the areas with coarse sand sublayers extended to more than 8 cm depth. Approximately 40% of diatoms were present in the topmost 2 mm layer. The subsurface portion of diatom cells on average was concentrated within the layer with Eh values ranging from 0 to –80 mV. Eh values below –100 mV limited diatom penetration in deep anoxic sediment layers. The deep portion of diatom populations consisted basically of dividing cells. A cytological analysis of diatom cell distribution showed that the proportion of cells in the different phases of mitosis increased with increasing depth, and reached 80 to 90% at a depth of 2 to 3 cm. The regular presence of dividing diatom cells almost exclusively in aphotic anoxic sediments was noted first. The study of the dynamics of microphytobenthic vertical distribution revealed active diurnal vertical migration depending on temperature, light and tide regimes. The frequency of doublet cells (FDC) in epipelagic diatom populations was in inverse proportion to cell concentrations in the photic zone. Diatom division was registered only during incubation in the porewater, which was rich in inorganic nutrients and dissolved organic matter. We suppose that a more stable habitat with higher concentrations of nutrients (especially nitrogen) in their more reduced forms (NH_4^+ instead of NO_3^-) provides more favourable conditions for cell growth and division at the depth of several cm within the sediment compared, to the surface layer. Migration activity of diatom algae is an adaptation which permits cells to consume energy and to undergo fission under optimum conditions in spatially disconnected zones.

INTRODUCTION

Diatoms are one of the major algal components of sand and mudflats (e.g. MacIntyre et al. 1996). The location of these microalgae within the thin photic zone of bottom sediment is determined by their photosynthetic activity. However, there are also numerous reports of viable microalgae cells or their photosynthetic pigments at significant depths, down to several 10s of cm in the aphotic anaerobic zone in the different habitats, including in littoral and sublittoral bottom sediments of marine and freshwater basins (e.g. Grøntved 1962, Pamatmat

1968, Steele & Baird 1968, Fenchel 1969, Wasmund 1969, Steele et al. 1970, Fenchel & Straarup 1971, Branch & Pringle 1987, MacIntyre et al. 1996).

To explain the presence of photosynthetic algae in aphotic anaerobic sediment zones, various hypotheses have been proposed: passive and active movement of organisms within the bottom sediments. It has been suggested that microalgae penetrate into the deeper sediment layers either during sediment resuspension (Steele et al. 1970, Gargas 1970, 1971, Round 1979, Baillie & Welsh 1980, Branch & Pringle 1987, MacIntyre et al. 1996) or by vertical movement in undisturbed sed-

*Email: igp@stel.sebastopol.ua

iments. There are numerous reports of the synchronic movement of microphytobenthos in sediment with similar conclusions. Benthic microalgae reach the surface of the sediment during a daytime emersion period and bury themselves deeper into sediment layers with the receding tide and/or the onset of night (e.g. Fauré-Fremiet 1951, Ganaparti et al. 1959, Perkins 1960, Palmer & Round 1967, Paterson & Underwood 1990, Robak & Kühl 1997, Kingston 1999). Fluctuations in photosynthetic rate, production and concentration of chlorophyll *a* in the surface layer of the soft sediment coincide with the phases of tidal and day:night cycles (Marshall et al. 1971, Brown et al. 1972, Raiux-Gobin 1985, Guarini et al. 2000, Serôdio & Catarino 2000). Such fluctuations are considered by these authors to be connected with microalgae vertical migration.

Fundamental questions concerning vertical distribution of microalgae in the sediment are: Why are photoautotrophs found outside the photic zone? What is their physiological state? How do photoautotrophs adapt to a long absence of light in oxygen-free conditions?

In this study, we investigated the vertical distribution of epipellic diatoms and their physiological activity within the sediment to better understand their behaviour mechanisms and their cell cycle regulation under environmental conditions which are atypical for photoautotrophs in the aphotic zone of intertidal sediments.

MATERIALS AND METHODS

Site description. The study was carried out in the gently sloping, low-energy, intertidal sandflat of the Chernaya River Estuary (Kandalaksha Gulf, White Sea, Russia) (Fig. 1) during the summers of 1994–2001. The sediment was fine-grained sand (modal particle size of 0.1 to 0.25 mm), slightly silty (up to 15% of the aleuropelite fraction) and oligosaprobic (organic carbon content up to 4% of the sediment dry weight). The upper boundary of the reduced zone (redox potential, $E_h < 0$ mV) was found at a depth of 1 to 6–8 cm according to the type of sublayer (clay or coarse sand); the boundary of the photic zone (>1% of total solar radiation) extended from 2.5 to 3.0 mm. The emersion time at the sampling site was ca. 4 h during the single semi-diurnal tidal cycle and the tidal range was ca. 1.6 m. A detailed survey examining the environmental characteristics of this sandflat was carried out by Burkovsky (1992).

Sampling procedures. Samples were collected from undisturbed sediments without infauna, stones or other physical irregularities on the middle intertidal area. A previous study revealed that such habitats are preferable for microphytobenthic development (Saburova et al. 1995). Samples were collected from microalgal patches (more than 10^3 to 10^4 cells cm^{-2}) after preliminary sampling to estimate microalgal spatial distribution. Sediment cores were collected during the daytime emersion using plexiglass corers with an internal diameter of 2.6 cm.

Vertical distribution profiles of epipellic diatoms were determined by collecting 21 cores (15 cm deep) during June to September, 1994 to 1998. The sediment cores were sectioned every 2 mm and then at 5 mm intervals. The tops of the cores (upper 5 cm, in several cases the upper 10 cm depending on sediment type) were used for the analysis.

To study the microalgae response to sediment burial, a field experiment was conducted July 17 to 22, 1992. A 4 cm layer of sterilized sand was placed over the natural sediment surface during the daytime emersion. A plastic frame prevented the added sediment layer from being washed out (the experimental phases are shown in Fig. 4). One core from both the sublayer natural sediment and the added upper layer of sand were collected on Days 1 and 5. Sediment cores were sectioned at 5 mm intervals to a depth of 4 cm. The dynamics of diatom vertical distribution were analyzed.

The vertical migration of epipellic diatoms in the sediment was investigated from June to September 1995–2001 in 14 time series (Table 1). These studies represented 2 different situations occurring in this polar region: the so-called ‘white-nights’ (a night

without full darkness) when there is no true day:night cycle (up to July) and normal day:night cycles (from August). The bottoms of the plexiglass corers with intact sediment cores were sealed, placed in the boxes with seawater and exposed to natural solar radiation intensity and temperature. Approximately 3 cm of water overlaid the sediment at the time of the experiments. Previous studies have revealed that microalgae migration rhythms do not change after the removal of sediment cores from natural conditions. Algal cells continued to migrate towards and away from the sediment surface in the absence of external stimuli under laboratory conditions for several days (e.g. Perkins 1960, Palmer & Round 1967, Serôdio et al. 1997). Changes in the vertical profiles of the diatoms were determined by an analysis of randomly chosen cores every 2 to 6.5 h during the observation period. The cores were sectioned into 2 layers (0 to 3 and 3 to 50 mm, corresponding to the photic and aphotic zones of this sediment type—Series 2 and 6) or into 0 to 3 mm and then at 10 mm intervals to a depth of 53 mm (Series 3 to 5 and 7 to 14). In Series 1 sediment cores were sectioned at 2 mm intervals to a depth of 50 mm.

Enumeration of diatom cells. The modified method of Uhlig (1968) with filtered seawater instead of ice was used to extract the microalgae from the sediment. Microalgae cells were counted *in vivo* in culture dishes at a magnification of 56× with a Lomo MBS-9 stereomicroscope in randomly selected fields of view immediately after the extraction. The most abundant and large (60 to 100 µm) species of epipellic diatoms (*Pleurosigma aestuarii*, *Donkinia recta*, *Entomoneis paludosa*, *Plagiotropis lepidoptera*, *Navicula humerosa*, *Hantzschia virgata*) were analyzed.

Cell cycle study. In diatoms generally, there is a 1 to 2 h post-cytokinesis stage between mitosis and G1, devoted to the formation of the silicon frustule, during which the daughter cells remain attached and grow in size (Vaulot et al. 1986). The number of such doublet cells within a population was determined microscopically *in vivo* while counting total diatom abundance. At least 300 cells were examined per sample.

A total of 19 intact sediment cores were collected for cytological analysis during June to August, 1995–1999. Cores were sectioned into 5 mm thick layers up to 35 mm and fixed with Navashin's fixative (Jensen 1962). The sequential decantation method was used to separate diatom cells from the sediment particles. Cells from each layer were mounted on glass microscope slides and stained with carmine acid according to Schneider (Jensen 1962). The cell cycle phase for each cell was determined by the degree of chromatin condensation in the cell nucleus at a magnification of 1500× with a JenaLumar microscope (Jena). Nuclei of large (60 to 100 µm) epipellic diatoms were close-cut separated according to cell cycle stage. From the caryological analysis we distinguished 3 well-defined cell cycle stages: interphase (I), mitosis (M) and cytokinesis + post-cytokinesis (C). Weakly stained nuclei with clearly visible chromatin grains were attributed to I; during M strongly stained and packed nuclei were observed; doublet nuclei within 1 cell or doublet cells were determined as C. Four abundant epipellic diatom species (*Pleurosigma aestuarii*, *Donkinia recta*, *Entomoneis paludosa* and *Plagiotropis lepidoptera*) were selected for examination.

Effect of environmental factors on diatom division. To define the optimum conditions for vegetative division of epipellic diatoms a laboratory experiment was

conducted in July 1998. The topmost 3 mm photic layer of the natural undisturbed sediment was collected during the daytime emersion, when the maximum concentration of diatoms on the surface was observed. Plexi-glass corers with the collected sediment were exposed to different conditions (phases of the experiment are shown in Table 5). The diatom cells were extracted from the sediment after exposure to these various conditions and the intensity of division (frequency of dividing cells) was estimated.

Physical sampling. Redox potential (Eh, mV) was measured using a pH-meter equipped with a 0.5 mm combined platinum electrode at 2 mm depth intervals. Grain-size analysis was performed on the upper 10 cm of the sediment at 0.5 cm depth intervals. The dried sediment was sieved onto a separator with mesh sizes 0.1, 0.25, 0.5, and 1 mm. The environmental conditions (temperature [°C], solar radiation intensity [lux] of the sediment surface, and tidal cycle) during the periods of diatom vertical migration observations were recorded. The tidal cycle values (h) were expressed as time from beginning of emersion (0 to 4 h: emersion; 4 to 12 h: submersion; 2 h: low water; 8 h: high water).

Data analysis. As most diatoms studied show high microspatial variability (Saburova et al. 1995), diatom abundance in each layer was expressed as a percentage of total density per core, to account for variability among the replicate cores. The dominating diatom species in each core were used for the analysis.

Diatom vertical distributions were presented as the percentage of the total population counted in each layer of the core. Vertical movements of microalgae within the sediment were estimated from the dynamics of the surface abundance. To estimate the vertical pattern of a cell cycle the results for each diatom population were expressed as the percentage of cells in each stage of the cell cycle from the total number of cells in each layer. The frequency of doublet cells (FDC) for each diatom population was calculated as a percentage of the doublet dividing cells from the total number of cells in the core and used as an indicator of vegetative cell division intensity.

Correlation analysis (Pearson's correlation coefficient) was performed to determine whether there were any significant changes in diatom cell cycle patterns with depth. We used stepwise multiple regression analysis, including momentary and daily (serial) mean values of temperature and solar radiation intensity of the sediment surface and tide cycle and all their combinations, to evaluate relationships between the measured factors and relative abundance of diatom cells in sediment surface. The 2-sample χ^2 -test was employed to compare the frequency distribution of cell cycle stages between the surface and deep sediment layers. In other cases Student's *t*-test was

used to check significance of the differences between the means. A critical *p*-value of <0.05 was always applied.

All statistical tests and procedures were undertaken using SYSTAT for Windows, Version 7.0 (SYSTAT) and SigmaPlot for Windows, Version 4.01 (SPSS).

RESULTS

Vertical distribution of diatom cells

Two different types of habitats were present in the studied intertidal sandflat: sediment with clay, and sediment with coarse sand as a sublayer (Types A and B, respectively). These sublayers occurred deeper than 10 cm (Burkovsky 1992). The vertical distribution of epipellic diatom total abundance in comparison with the vertical Eh profiles and granulometric composition of the different types of the sediment are shown in Fig. 2. The vertical distribution of diatoms was not uniform: approximately 40% of the diatoms were present in the topmost 2 mm layer, whereas a significant percentage (more than 60%) was found in deep layers of the sediment. Maximum recorded depths of penetration of viable diatom cells into the sediment were 42 mm in Type A sediment and 83 mm in Type B. The subsurface portion of diatom cells was concentrated on average within the layer with Eh values from 0 to -80 mV, at a depth of around 15 to 35 mm for Type A and 35 to 70 mm for Type B. Eh values below -100 mV limited diatom penetration into the deep anoxic sediment layers.

The granulometric composition was similar in the topmost 6.5 cm layers for both sediment types. Significant differences were observed deeper than 6.5 cm. The fine fraction (<0.25 mm) increased 1.3× within the 65 to 100 mm layer in comparison with the topmost 0 to 65 mm layer in Type A sediment. In contrast, the coarse fraction (>0.5 mm) content in Type B sediment increased more than 2×.

Division of diatom cells in the deep aphotic zone

Vegetative cell division has been observed in large living diatom cells without cytological stains (Cox 1981, Pickett-Heaps 1998). Whilst counting living diatom cells from different sediment layers, we often found clearly visible doublet cells in the cytokinesis and post-cytokinesis stages (>200 observations were made between 1994 and 2001) often in significant numbers (up to 60–80% of the total number of cells in a layer). These cells were almost exclusively associated with the aphotic anoxic zone of the sediment.

Fig. 2. Vertical profiles of epipellic diatom total abundance (grey horizontal bars) and Eh (—○—) (left plots) and granulometric composition of sediments from topmost 65 mm and 65 to 100 mm layers (vertical bars, right plots) from different intertidal sandflat sites. Sediments with (A) clay sublayer and (B) coarse sand sublayer. A total of 33 cores were collected during daytime emersion periods in July 1992, July 1994 and June 1995. Error bars represent SE of the mean within replicate cores: (A) 8 and (B) 5 for diatom abundance estimation; 5 and 7 for Eh and 4 and 5 for granulometric composition estimations

FDCs varied strongly among diatom species and cores collected at different times of day (Table 2). Three examples of the daily pattern of the nondividing and dividing cells in the vertical distribution of *Donkinia recta* are shown in Fig. 5.

Percentages of the diatom abundance in 2 mm thick layers from the sediment surface to the depth of 35 mm were compared to the patterns of cell cycle stages within each 5 mm thick sediment layer (Fig. 3). All the diatom species examined demonstrated similar vertical distribution: about 40 to 60% of the cells were present in the photic zone, while the other parts of the populations were dispersed over the aphotic zone down to 35 mm (Fig. 3, left-hand panels). Patterns of cell cycle stages in the surface and deep parts of the population

were not similar. The percentage of nondividing cells (I) decreased and the percentage of dividing cells (M + C) increased with depth. Similar vertical distributions were observed in each diatom species (Fig. 3, right-hand panels).

Table 3 shows the mean percentage of cell cycle stages in the topmost 5 mm (corresponding to the photic zone) and the deeper 5 to 35 mm layers (the aphotic zone). The patterns of the cell cycle stages between the upper (photic) and deep (aphotic) sediment layers were significantly different (2-sample χ^2 -test; $p < 0.001$) for all diatom species examined (Table 3). The percentage of cytokinetic cells in *Pleurosigma aestuarii* and *Donkinia recta* correlated significantly with depth. A noticeable tendency was obtained in the case of *Entomoneis paludosa*. The percentage of cells in the interphase correlated significantly and negatively with depth in these 3 diatom species. There was no linear correlation between frequency of mitosis and depth, except for *E. paludosa*. Insignificant correlation coefficients for *Plagiotropis lepidoptera* may have resulted from insufficient data.

Vertical movement of diatom cells within the sediment

Response to burial in the sediment

The migratory behaviour of the epipellic diatoms buried in the sediment is shown in Fig. 4. Microalgae demonstrated the ability to avoid unfavourable conditions by long-term burying. The experiment estimated the maximum rate of microalgae movement at 1.7 mm h⁻¹. We detected buried cells on the surface of the sterilized sand (4 cm layer) within the first 24 h of the experiment. Of the initial microalgae abundance, 61% moved into the upper sediment layer after 24 h. Upward migration of diatoms leads to practically full renewal of their disturbed vertical distribution over 5 d. However, 22.4% of the cells were still in the buried layer of the sediment (40 to 75 mm) 5 d later. Vegetative division of the epipellic diatoms occurred only within natural sediment, and stopped after the migration of cells into the upper sterilized sand.

Table 2. Percentage of frequency of doublet cells (FDC) for different epipellic diatoms, n: number of replicates

Diatom species	Mean ± SD	Min	Max	n
<i>Entomoneis paludosa</i>	8.26 ± 7.80	1.21	36.4	198
<i>Pleurosigma aestuarii</i>	15.72 ± 19.10	0.87	72.2	37
<i>Donkinia recta</i>	19.30 ± 17.22	0.63	71.4	56

Fig. 3. Vertical profiles of relative abundance (left-hand panels; mean \pm SE) and cell cycle patterns of epipellic diatoms. Cores were collected in June to September, 1994–1998. The length of each bar in left-hand panels is the percentage of the total population found in each depth interval. The length of each bar in right-hand panels is the percentage of the total cell number found in each layer. Error bars represent SE for replicate cores (left-hand panels) and replicate layers (right-hand panels). Number of replicates (n) was indicated within plots

Vertical migration of epipellic diatoms in the sediment

Analysis of daily patterns of microalgae vertical distribution and of environmental factors (solar radiation intensity, temperature and tidal cycle) during 14 time series (Table 1) revealed similar vertical migration of all the examined epipellic diatoms.

A detailed analysis of the vertical distribution dynamics was conducted for *Entomoneis paludosa*, the most abundant diatom (on average 10^4 cells cm^{-2}) on the examined intertidal sandflat. The resulting step-wise multivariate regression model explaining 39% of the total variation revealed T_{ser} , H and $T \times L/T_{\text{ser}}$ variables to be significant (Table 4). *E. paludosa* demonstrated circadian rhythms of vertical migration within the sediment. Relative abundance of the cells in the sediment surface reached its maximum on warm days during low water. The colder the day, the higher the

combined effect of temperature and light exposure of the sediment surface.

Epipellic diatom rhythms of division

We recorded epipellic diatom rhythms of division in each time series during our observations of vertical migration. A certain portion of the diatom cells was always undergoing vegetative division (Table 2). Dividing cells of epipellic diatoms were associated with the aphotic deep layer of the intertidal sediment. However, the frequency of the dividing cells varied greatly. A typical example of the vertical profiles for *Donkinia recta* during the day is shown in Fig. 5. *D. recta* cells were concentrated on the sediment surface during the daytime emersion (76.2% in the topmost 2 mm) and went deeper into the sediment at nightfall (Fig. 5).

Table 3. Analysis of upper photic layer (0 to 5 mm) versus deep aphotic layer (5 to 35 mm) differences in frequency distribution of cell cycle stages for 4 epipellic diatoms. Cell cycle stages: I, interphase; M, mitosis; C, cytokinesis and post-cytokinesis; m, total number of examined cells. The results of 2-sample χ^2 -test for differences between cell cycle stage patterns in upper and deep layers and the Pearson's correlation coefficients for the relationship between stages of the cell cycle and depth are given. All χ^2 -values are significant at $p < 0.001$ level, $df = 2$ and Pearson's correlation coefficients in **bold** are statistically significant at $p < 0.05$

Diatom species	Frequency distribution of cell cycle stages (mean \pm SE)		2-sample χ^2 -test values	Pearson's correlation coefficient

C	0	9.09 \pm 4.18		-0.058
m	146	124		

After descending, cells of *D. recta* started to divide intensively. FDC varied from 4.76% during the daytime emersion up to 25.9–43.3% during the nighttime emersion and submersion.

Frequencies of the dividing cells in the examined diatom populations were in inverse proportion to the number of cells in the photic zone (Fig. 6).

Optimum environment for epipellic diatom division

The undisturbed topmost sediment layers containing microalgae were exposed to different conditions to determine the optimum environment for epipellic diatom cell division. The results are shown in Table 5. Vegetative division was registered only during incubation in porewater, which was rich in inorganic nutrients and DOM. As can be seen from Table 5, negative Eh values were not necessary for successful vegetative division of the diatom cells. However, in contrast with laboratory conditions, high concentrations of the nutrients in interstitial water have been observed in deep anoxic layers of natural intertidal sediments (e.g.

Fenchel 1969, Martens et al. 1978, Langner-van Voorst & Höpner 1996, Landén & Hall 1998).

DISCUSSION

Benthic microalgae are typically associated with the topmost sediment layer corresponding to the photic zone (e.g. Hopkins 1963, Fenchel 1969, MacIntyre et al. 1996). The depth of a 1% light level in the sediments varies from 0.1 to 13.2 mm and depends on the granulometry and organic content of the sediments (MacIntyre et al. 1996). Nevertheless, viable cells and/or chlorophyll *a* have been observed to a depth of 10 cm (Grøntved 1962, Pamatmat 1968), 14 to 15 cm (Fenchel 1969, Fenchel & Straarup 1971), and 20 to 30 cm (Steele & Baird 1968, Branch & Pringle 1987) on intertidal sandflats; to a depth of 30 cm (Steele et al. 1970) on a subtidal sandflat and 7.3 to 9.5 cm (Wasmund 1969) on a freshwater subtidal sandflat.

Typical patterns of diatom vertical distribution in sediment examined during the daytime emersion included the surface-associated peak of abundance formed by 40 to 60% of

microalgae total abundance (Figs. 2 to 5). The subsurface portion of cells was dispersed within the sediment depending on the sublayer properties, which determined the depth of the redox zone location. Comparison of the vertical profiles of diatom abundances in Fig. 2A,B shows that the cells were dispersed over a greater range of depths in Type B sediment (83 mm), than in Type A (42 mm).

Cell cycle patterns of epipellic diatoms along depth (Fig. 3) revealed major differences between the surface- and the subsurface-associated portions of diatom populations. The predominance of nondividing cells near the sediment surface and the increase in the percentage of dividing cells with depth, as well as occurrence of cytokinetic cells only in deep layers (Fig. 3, Table 3), led us to assume a physiological heterogeneity of the microalgal populations at different depths of the sediment. A border between the physiologically different portions of diatom populations was located near the redox potential discontinuity layer (oxic/anoxic interface, Eh = 0 mV). We believe the present study to be the first report on the occurrence of diatom cell division in only the deep layers of intertidal sedi-

Fig. 4. Dynamics of epipellic diatom vertical distribution under artificial burial conditions: within natural sediments (lower panels) and sterilized sand (upper panels). A core from each type of the sediment (40 mm of each) was collected during July 17 to 22, 1992

ments. Correlation analysis showed that percentages of interphasic and cytokinetic cells were significantly correlated with depth: the percentage of interphasic cells decreased and that of dividing cells increased with depth (Table 3).

Our investigations showed that the epipellic diatoms were able to avoid unfavourable burial conditions by active upward migration to the surface. Nevertheless, the initial vertical distribution was not restored even 5 d after the start of burial, and a portion of cells remained in the buried layers (Fig. 4). We assume that the establishment of destroyed vertical gradients of the sediment environment was a slow process, which allowed diatoms to expand their zone of the habitation whilst extremely negative Eh values were absent.

We observed rhythms of vertical migration of diatoms close to those described earlier (e.g. Fauré-Fremiet 1951, Palmer 1960, Perkins 1960, Hopkins 1963, Round & Palmer 1966, Robak & Kühl 1997, Kingston 1999). The diatoms reach their maximal concentration on the sediment surface during daytime emersions and begin to dip into the sediment with the rising tide, reaching a maximal concentration in the aphotic zone at night (Fig. 5).

Temperature and solar radiation intensity in combination with the tidal cycle are the main factors that regulate amount of epipellic microphytobenthos migration activity (Table 4). The variability of these factors is determined by recurrence: temperature and light intensity regimes have similar diurnal and seasonal rhythms. The tidal cycle in the region studied is semi-diurnal with a time alteration of 40 min every 24 h and also has a 14 d or semi-lunar rhythm with alternating spring and neap tides. The superimposition of the

tidal and day:night cycles of different periods causes variability in the intertidal light and temperature regime and determines the migration rhythms of the diatoms.

Diatom vertical migration and division rhythms occur in an antiphase: the daytime maximum of cell abundance in the photic zone corresponds to a minimum of division activity, whereas the nighttime mini-

imum of cells on the surface corresponds to the peak of division in the aphotic zone (Figs. 5 & 6).

Previous reports have shown how the nutrient properties of porewater from the deep layers of the intertidal sediments (Polikarpov & Saburova 1990) or from the reduced zone of the Black Sea (Polikarpov et al. 1986) affect the development of diatom algae. In our field work, we identified dividing diatom cells exclusively at a depth of several cm in oxygen-free and strongly reducing conditions. However, the results showed that these conditions were not necessary for microalgal division (Table 5). Apparently, microalgae can find the necessary nutrient concentrations for their successful development in the most acceptable forms (NH₄⁺ instead of NO₃⁻) only in the deep layers of the sediment (Fenchel 1969) and, as a consequence, microalgae have to develop resistance to potential unfavourable factors in this zone (Moss 1977).

Preliminary work on the response of the epipellic microphytobenthos to changes in the vertical structure has shown that any physical disturbance will prevent cell division, although microalgae continue to migrate (Saburova 1995).

Our data support the hypothesis that migration activity of diatom algae is a forced adaptation, which permits cells to consume energy and to divide under optimum conditions in the spatially disconnected zones.

Comparing the diatom migration activity in 2 separate layers, it is necessary to remember that the less stable photic layer is part of both the sediment-water and sediment-air interface. As such, the photic layer is exposed to dramatic changes in environmental factors, and to significant grazing pressure (the so-called 'stressful zone'). However, the photic layer is also the zone where microalgae photosynthesis takes

place. The dynamics of such competing forces result in a constant movement of epipellic microalgae within the sediment, as if they are 'searching' for the optimum zone along the gradient of these factors.

CONCLUSIONS

Vertical stratification of the sediment, as well as the ability of microalgae to actively migrate vertically with a cycle close to circadian rhythms, are the factors determining the distribution of epipellic diatoms within the sediment.

These new observations, i.e. that epipellic diatom cells divide exclusively in the aphotic zone and that cytokinetic cells are absent from the surface of the sediment, demonstrate that the vertical migration of these microalgae allows them not only to avoid unfavourable conditions, but also to move into the deep layers of the sediment, which are, for several reasons, the necessary locations for mitosis and cytokinesis.

The results from our study and from previous studies have been combined and presented as a general scheme to illustrate our hypothesis (Fig. 7).

The migration behaviour of epipellic diatoms is regulated by 2 complex factors, an exogenous one (the set of intertidal flat environmental conditions) and an endogenous one (the cell cycle). The cells born as a result of division at a depth of 2 to 3 cm need energy and nutrition to continue their cell cycle. Energy is accumulated during photosynthesis in the photic zone of the sediments. However, the optimum conditions

for photosynthesis develop at the sediment surface during daytime emersion. There are 1 or 2 short periods of about 4 h d^{-1} when the optimum conditions for migration are present and all the cells that have completed mitosis begin to move upwards. Having accumulated sufficient energy during photosynthesis, most of the microalgae migrate to the deep layers of the sediment at the beginning of submersion, i.e. evening.

Cells in the deep layers of the sediment find themselves in more favourable conditions for cell cycle development. Heterotrophic metabolism (Bunt 1969, Hellebust & Lewin 1977) enables them to obtain the necessary substances for their growth from DOM-rich porewater (Landén & Hall 1998) as opposed to nutrient-deficient surface water. The specific physical and chemical conditions in the deep sediment layers produce inorganic nutrients in more reduced forms (Fenchel 1969, Martens et al. 1978, Langner-van Voorst & Höpner 1996), making their consumption more energetically profitable (Parsons & Harrison 1983). All these factors contribute to successful cell growth and division. After division, the cells remain in the deep layers of the sediment waiting for the next period of migration to the surface (Fig. 7).

The process of cyclic migration is not totally synchronous: some of the cells are always in antiphase to the general flow, remaining in the aphotic zone when the main body migrates to the surface, and vice versa. Biological rhythms do not determine the behaviour of an organism in a concrete situation, but play the role of a barrier, ruling out the possibility of a particular behavioural act under particular concrete conditions.

The concrete conditions and the internal readiness of the organism regulated by its biological clocks (cell cycle) determine the degree of behavioural expression (Aschoff 1981).

Natural populations of microalgae differ significantly from synchronized laboratory cultures. Separate cells within the sediment can gain an advantage due to an irregular microdistribution of different environmental factors, and take the lead in development as compared to their neighbours and vice versa. However, instead of a continuous rotation of cells in different stages of their cell cycles, we observe synchronic related to the regulating effect of exogenous rhythms. In other words, the end of mitosis starts the cycle, and environmental factors regulate cycle rate and cell behaviour in the process.

Acknowledgements. The authors express their appreciation to Prof. Kirill M. Khailov (Institute of Biology of the Southern Seas), Dr. Andrey Azovsky (Moscow State University) and Mr. Sergey Kropotov (Marine Hydrophysical Institute) for criticism, and Dr. Sc Ludmila V. Iliyash (Moscow State University) for her fruitful cooperation. We thank Dr. Michael J. Wade (Wade Research) for English language text improvement and Mrs. Marina Fadeeva for helpful comments on the manuscript. Critical evaluations of and valuable suggestions regarding an earlier version of the manuscript by 4 anonymous reviewers were extremely helpful. We are very grateful to Prof. Otto Kinne and the Otto Kinne Foundation for support of the present work.
