

Size-dependent variation in the functional role of the parrotfish *Scarus rivulatus* on the Great Barrier Reef, Australia

Roberta M. Bonaldo*, David R. Bellwood

ABSTRACT: Biodiversity loss and fishing-induced changes in the size distributions of fishes can impact ecosystem function on coral reefs. These changes have led to an urgent need for studies on the particular roles of species to underpin effective coral reef management. The present study focuses on the feeding ecology of 6 size classes (from 2.5 to 30 cm total length) of *Scarus rivulatus* (family Labridae), one of the most abundant parrotfishes on the Great Barrier Reef, Australia. Individuals in all 6 size classes strongly selected the epilithic algal matrix for foraging and rejected other substratum types, including coral, macroalgae and sand. The 6 size classes also had similar feeding rates (bites min^{-1}) and diel feeding patterns, with higher feeding activity during the afternoon. However, the size of grazing scars by *S. rivulatus* differed significantly among the 6 size classes, with small individuals scraping a greater substratum area per unit biomass and larger individuals taking a greater volume of material per unit biomass. Thus, biomass cannot be viewed as a proxy for ecosystem impact; different sized individuals of *S. rivulatus*, and probably other parrotfish species, have a markedly different impact on the reef substratum. Selective harvesting of large individuals will therefore change the functional role of this species. These results emphasize the importance of considering the size of individuals when evaluating the role of reef species in ecosystem process. These intraspecific functional differences will be critical when formulating reef management strategies and evaluating the impact of fishing activity on reef ecosystems.

INTRODUCTION

The loss of biodiversity and the modification of size-frequency distributions through fishing activity can have direct consequences for marine ecosystem function (e.g. Hughes et al. 2005). On coral reefs, these changes have highlighted the urgent need for studies on the particular role of reef species in ecosystem processes that can underpin effective coral reef management (McClanahan et al. 1997, Bellwood et al. 2003, Hughes et al. 2003, Mumby et al. 2006, Wilson et al. 2006). In this context, studies on the functional role of species have become an important prerequisite for

coral reef management, since they can provide important information about the extent of functional redundancy and potential coral reef resilience.

Although there has been considerable interest in the functional role of species, relatively few studies on this subject have been conducted on Indo-Pacific coral reefs, one of the world's most diverse and threatened ecosystems. For example, although herbivory is recognized as one of the key factors shaping the benthic community structure of coral reefs (Lewis & Wainwright 1985, McClanahan et al. 1997, McCook 1999, Burkepile & Hay 2006, Littler & Littler 2006, Mumby et al. 2006), literature on the quantitative ecosystem

impacts of individual herbivorous taxa on these systems is limited (McManus & Polsenberg 2004). This small dataset of measured ecosystem impacts for individual taxa partly reflects the tendency for herbivory to be viewed as a uniform process (cf. Choat 1991). However, several studies have shown that grazing by distinct groups of herbivorous fishes can have different effects on the algal community succession (e.g. Hixon & Brostoff 1996, Ceccarelli et al. 2005), with individual species having markedly different functional roles (e.g. Bellwood et al. 2006, Hoey & Bellwood 2007).

Very little is known of intraspecific variations on the functional role of reef fishes on Indo-Pacific reefs since most studies describe functional roles as a species-specific trait. However, a key question remains: Does size affect the functional role of fishes on coral reefs? Many coral reefs around the world suffer from a depletion of fish stocks, especially of large individuals, the main target of commercial and artisanal reef fisheries (McClanahan et al. 1997, Nyström et al. 2000, Bellwood et al. 2003, Floeter et al. 2006, Mumby et al. 2006). As a consequence, on reefs with intense fishing there is an effective reduction in the overall size structure of fishes. This has unknown functional implications. During its development, a fish can greatly change its size, shape, colour and behaviour; thus, individuals of a same species may play markedly different functional roles in the ecosystem throughout their lives. Ontogeny is well known to be important in ecology, but it has not been evaluated from an ecosystem perspective on coral reefs (cf. Hoey & Bellwood 2007). This paper redresses this problem for the Indo-Pacific parrotfish species *Scarus rivulatus*.

The parrotfishes (Labridae; formerly Scaridae) are among the predominant reef herbivores in terms of population density, biomass and algal consumption, and are well known for their importance in the dynamics and diversity of coral reefs (McClanahan et al. 1997, Hughes et al. 2003, Bellwood et al. 2004, Mumby et al. 2006). Size-related changes in the functional role of individual parrotfish species have been studied in the Caribbean (e.g. Bruggemann et al. 1994a,b), but relatively few species have been examined on Indo-Pacific coral reefs (but see Bellwood 1988, Fox & Bellwood 2007).

Scarus rivulatus was selected because it is the most abundant scarid on the inner-shelf Great Barrier Reef, Australia (GBR), and may therefore exert a significant functional role in reef ecosystem processes (Fox & Bellwood 2007, Hoey & Bellwood 2007, Mantyka & Bellwood 2007a,b). In order to understand the impact of size on functional roles, this study characterized the feeding activity of 6 different size classes (from 2.5 to 30 cm total length) of *S. rivulatus* on an inner reef of the GBR. The specific aims were (1) to provide a broad

overview of the ontogeny of the feeding behaviour of *S. rivulatus*, (2) to quantify the feeding activity of 6 size classes of *S. rivulatus*, and (3) to evaluate the potential extent of ontogenetic variation in the impact of *S. rivulatus* on the reef substratum.

MATERIALS AND METHODS

Study site and general methodology. This study was conducted between February and July 2007 at Orpheus Island (18° 35' S, 146° 20' E), a granitic island in the inner shelf region of the GBR, approximately 20 km off the coast of North Queensland. Two sites within Pioneer Bay, located on the leeward side of the island, were used in the study. To standardize observations, all were conducted in the same reef zone (outer flat).

Feeding rates, substratum selection and the size of grazing scars (area and volume of material removed during feeding) were quantified for 6 size classes of *Scarus rivulatus*: 2.5 to 5 cm, 6 to 10 cm, 11 to 15 cm, 16 to 20 cm, 21 to 25 cm and 25 to 30 cm total length (TL). Observations on substratum selection and feeding rates were all conducted during the austral summer (February to March) to minimise temperature or seasonal effects. All observations were taken within 3 h of high tide to minimise the impact of tides.

Feeding rates. Observations on the feeding rates (bites min^{-1}) of individual size classes of *Scarus rivulatus* were carried out over 10 consecutive days by SCUBA divers. The observations were made over 4 periods during the day: morning (08:00 to 11:00 h), middle of the day (11:01 to 14:00 h), afternoon (14:01 to 16:00 h) and late afternoon (16:01 to 18:00 h). The sample unit was a 1 min period; divers recorded the fish's size class, the start time of the observation and the total number of bites taken. At least 30 ind. of each size class were followed during each period at each study site. No similarly-sized individual was followed over successive periods to minimize the risk of collecting non-independent data. Observations were discontinued if the fish showed a visible response to the diver.

Substratum selection. The substratum selection by different size classes of *Scarus rivulatus* was assessed by comparing the number of bites taken on each substratum type and the availability of that substratum at each site. Individuals were located during haphazard surveys at each site. Once a focal individual was located, it was classified into one of the 6 size categories and followed at a distance of at least 2 m until the fish was observed to bite the substratum. The substratum type was then classified into 5 categories: epilithic algal matrix (EAM, sensu Wilson et al. 2003), hard coral, macroalgae (*Sargassum* spp. and *Turbinaria* spp.), sand and soft coral. A total of 60 ind. of each size class

was observed for the substratum selection and only 1 feeding observation was recorded for each individual to maximize the independence of replicate observations.

Relative proportions of the components of benthic cover at each study site were obtained using a line-intercept method (Choat & Bellwood 1985). A 10 m transect tape was laid haphazardly across the reef substratum. At each 1 m interval along the tape, the diver recorded the nature of the substratum directly underneath the tape and at points 1 m perpendicular to the left and right of the tape. The substratum type was classified into the same categories used for the feeding bites of *Scarus rivulatus*. A total of 12 replicate 10 m transects were conducted at each of the 2 study sites ($n = 24$).

Grazing impact. The grazing impact of different size classes of *Scarus rivulatus* was assessed by measuring the grazing scars of individuals in each class. The term 'impact' herein refers to the immediate consequences of feeding activity, i.e. the removal of algal material, and does not necessarily reflect long-term changes to the community composition of the EAM. The nature (i.e. if fish bite exposed the substratum or not) and size (maximum area and volume) of grazing scars of *S. rivulatus* were measured by SCUBA divers, who followed focal individuals until the exact location of a bite could be seen. TL of the individual was estimated, exposure of substratum was recorded and maximum length (L_{\max}), width (W_{\max}) and depth (D_{\max}) of the grazing scar was measured with callipers. The size of grazing scars was calculated in terms of maximum area ($L_{\max} \times W_{\max}$, assuming a rectangle) and maximum volume ($L_{\max} \times W_{\max} \times D_{\max}$). The maximum depth of the scar was measured by the difference of the algal height inside and on the margin of the grazing scar. In order to provide an adequate comparison between the different size classes of *S. rivulatus*, all the grazing scar measurements were conducted on the same substratum type (dead coral matrix covered by EAM). At least 30 grazing scars of each *S. rivulatus* size class were measured and analysed per study site. Because of their reduced size, scars of some individuals in the smallest size class were observed in aquarium tanks and measured under a stereomicroscope.

Quantification of the feeding impact per unit body mass of the 6 size classes was based on the estimated total number of bites between 08:00 to 18:00 h multiplied by the size of an individual bite (area and volume) and divided by the body mass of each size class. Body length estimates were converted to biomass estimates using published length-weight relationships (Kulbicki et al. 2005).

Analyses. Feeding rates of *Scarus rivulatus* were compared using a 3-way ANOVA, with study sites, size

class and time of day as fixed factors. The number of bites of *S. rivulatus* per substratum type at the 2 sites was compared using a chi-square contingency table. Selection of foraging substrata by the 6 size classes was measured based on Strauss's linear resource selection index (L in Strauss 1979) and 95% confidence intervals (CI) were calculated.

The number of grazing scars exposing the substratum between the 2 study sites was compared using a chi-square contingency table. The number of grazing scars exposing the substratum among the 6 size classes was compared using a chi-square for goodness of fit. To check if there was a geometric relationship between fish and scar size, linear regressions were made of scar area to fish TL² and scar volume to fish TL³, with TL as the independent factor and scar size the dependent variable. We also calculated the slope of a log-log graph of scar area and fish TL², and scar volume to fish TL³ to examine the allometric coefficient of fish TL and bite size.

Size (area and volume) of grazing scars of different size classes was compared using a 2-way ANOVA, with study site and size class as the fixed factor on each test. In such analyses, study site and fish size class were the fixed factors and the substratum removal was the variable. The overall quantification of the feeding impact per unit body mass of the 6 size classes was compared using the compound errors around the mean for each size class. Compound errors for the impact variables (feeding rates, grazing scar size) for each size class were calculated using the 2-term version of Goodman's estimator, with mean substratum removal \pm SE per kg of fish and total number of bites $d^{-1} \pm$ SE as terms (modified from Bellwood 1995). Total bites d^{-1} is based on a 10 h day and the mean \pm SE feeding rate is calculated as the sum of the mean \pm SE feeding rates for each hour between 08:00 to 18:00 h for each size class.

Before all parametric tests, data were examined for normality and homogeneity of variance using the D'Agostino-Pearson test and residual analysis. No transformations were needed, since the data met the required assumptions. Where differences were found to be significant in an ANOVA, post-hoc tests (Tukey's HSD) were used to examine patterns.

RESULTS

There were no differences detected in the feeding rates of *Scarus rivulatus* between sites or among fish size groups, but there was a highly significant time of day effect (Table 1), with all size classes foraging less during early morning and exhibiting a feeding activity peak during the middle of the afternoon (Fig. 1). Most

of the individuals in the largest size class of *S. rivulatus* were terminal phase (TP) individuals, while the 4 smallest size classes were juveniles or initial phase (IP) adults. In terms of substratum selection, no differences were found in the distribution of the total number of bites per substratum type between the 2 study sites ($\chi^2_5 = 1.25$, $p > 0.9$). The 6 size classes also showed the same substratum selection pattern: a strong preference for EAM and rejection of other substratum types. The Strauss's linear resource selection index for substratum types overlapped for all size classes and the *S. rivulatus* selection index was therefore based on pooled size-class data (Fig. 2).

No differences were found between sites in the distribution of bite scars exposing the substratum among the 6 size classes ($\chi^2_5 = 1.0$, $p > 0.9$). However, the relative occurrence of grazing scars that exposed the substratum did differ among the 6 classes ($\chi^2_5 = 121.18$, $p < 0.01$), with an increase in substratum exposure with increasing fish TL (Fig. 3a). Small individuals (2.5 to 10 cm TL) usually only cropped the algal surface and their grazing scars were usually marked only by a

shallow depression in the EAM. In contrast, large individuals always removed all the algal cover from the substratum and exposed the calcareous surface.

Bite scar area was linearly related to TL^2 ($r^2 = 0.97$, $F_1 = 4114$, $p < 0.001$) and volume was linearly related to TL^3 ($r^2 = 0.97$, $F_1 = 7024$, $p < 0.001$). The slope of the log-log relationships of TL^2 to bite area and TL^3 to bite volume were 0.98 ± 0.01 and 0.93 ± 0.02 , respectively. Both were approximately isometric (with negligible negative allometry).

The area and volume of grazing scars were similar between the 2 study sites ($p > 0.70$ for both analyses), but differed among the 6 size classes, with larger fishes removing more area ($F_{5,186} = 1431$, $p < 0.001$) and volume ($F_{5,186} = 1585$, $p < 0.001$) than smaller individuals (Fig. 3a). The greatest differences in the size of grazing scars were observed in terms of volume (Fig. 3a).

Standardized EAM removal per kg of fish differed markedly among the 6 size classes. Large individuals removed the smallest substratum area per unit body mass but the largest EAM volume per body mass (Fig. 3b). Fundamentally, 1 kg of biomass of small individuals exhibited a different ecosystem impact to 1 kg of large individuals.

DISCUSSION

Scarus rivulatus exhibited limited among-size variation in most ecological variables, but when considered in terms of functional roles—especially per unit biomass—small and large individuals displayed a markedly different ecosystem impact. In terms of feeding frequencies, the patterns were very uniform; all *S. rivulatus* size classes fed more frequently during the middle of the day. This result is very similar to the daily feeding pattern of other nominally herbivorous reef fish species (Bruggemann et al. 1994b, Bellwood 1995, Zemke-White et al. 2002). The higher feeding frequency of herbivorous fishes during the afternoon has been explained by the better nutritional quality of algae at this time (Bruggemann et al. 1994b, Bellwood 1995, Zemke-White et al. 2002). This diel feeding pattern seems to be particularly relevant to species that feed on epilithic algae and detrital aggregations (Zemke-White et al. 2002), which is probably the case for *S. rivulatus* in the present study.

The present study found no significant differences in the feeding rates of the 6 size classes of *Scarus rivulatus*, which is in accordance with a previous study of this species at the same study site (see Fox & Bellwood 2007). However, these results contrast with a number of studies on the feeding activity of other parrotfish species, which have found that large individuals, especially TP males, usually have lower feeding rates than juveniles and IP adults (e.g. Bruggemann et al. 1994a, Van Rooij et al. 1996b, Bonaldo et al. 2006). In these studies, the differences were explained by the territori-

ality of TP males, which usually spend a lot of time patrolling feeding and breeding territories and evicting conspecifics. We propose 2 explanations for the similarities in the feeding rates of different size classes of *S. rivulatus*: (1) TP males of this species are not territorial and, thus, forage as frequently as juveniles and IPs; or (2) the area where both studies on *S. rivulatus* were conducted (Pioneer Bay, Orpheus Island) is a feeding area where TP males do not display territorial behaviour. The latter hypothesis is supported by previous studies on parrotfish species in the Caribbean, which found that the behaviour of TP males is highly variable depending on the location of individuals (e.g. Van Rooij et al. 1996a). However, further investigations on the social system of parrotfishes in the GBR are needed.

Substratum selection was also similar with the 6 *Scarus rivulatus* size classes; all selected the EAM and strongly rejected macroalgae. The EAM is widely recognized as a substratum rich in sediment and detritus and is of high nutritional value (Crossman et al. 2001, Purcell & Bellwood 2001, Wilson et al. 2003). In contrast, macroalgae are widely recognized as having many characteristics (e.g. secondary compounds, low nutritional value) which may deter feeding by fishes (Hay 1991). Our results highlight the importance of EAM as the main feeding source of many herbivorous reef fish species and support previous studies, which found that many 'herbivorous' reef fishes (nominally herbivorous fishes *sensu* Choat et al. 2002) feed mostly on detritus and the EAM rather than macroalgae (e.g. Choat et al. 2002, Wilson et al. 2003, Crossman et al. 2005). Moreover, our results provide direct *in situ* support of experimental observations that *S. rivulatus* avoids macroalgae (Mantyka & Bellwood 2007a,b).

The similarities in the diel feeding patterns and selection of feeding substrata among the 6 size classes of *Scarus rivulatus* are also in accordance with the findings of previous studies on the feeding ecology and behaviour of other parrotfish species (e.g. Bruggemann et al. 1994c, Bonaldo et al. 2006). These results suggest that many aspects of parrotfish feeding do not change throughout the parrotfish life cycle. However, while some patterns apparently do not change as these fishes grow, others do—especially those related to the impact of their jaws. For example, a number of studies on the feeding ecology of parrotfishes on both Atlantic and Pacific reefs have found significant differences in the impact of different size classes on the reef substratum (Bruggemann et al. 1994b, Fox & Bellwood 2007). These differences suggest that distinct size classes of parrotfishes may play different roles in shaping the benthic community structure.

In the present study, large *Scarus rivulatus* individuals left grazing scars markedly larger in volume than grazing scars produced by small individuals and usu-

ally removed not only the algae and associated particulate material, but also dislodged small fragments of the underlying consolidated reef matrix and exposed the calcareous surface. Small *S. rivulatus*, however, usually only cropped the algal surface and had little or no visible effect on the EAM or consolidated substratum. A similar pattern has been seen in 2 Caribbean species, in which large individuals produced bites with visible grazing scars up to 4 times more frequently than small individuals (Bruggemann et al. 1994b). Large parrotfish individuals seem to affect both algal cover and the underlying substratum, and are responsible for the effective removal of algae and for opening new colonization sites on the reefs. Such variation shows that different sized parrotfishes may differ not only on their quantitative impact on the substratum (the grazed area), but also on how they influence the benthic structure of reefs (the extent and severity of algal removal).

This difference among size classes is most clearly exemplified by the standardized data: area and volume removed per kg of fish. The EAM volume per kg of large individuals is much larger than the volume per kg of small individuals, whereas small individuals graze a much larger area of substratum per unit body mass. Thus, the importance of these small individuals probably lies in their activity of cropping the algal surface, which may be responsible for controlling algal height. Thus, different sized individuals of parrotfishes may have markedly different roles in shaping the benthic community structure.

The functional differences in the grazing effects of small and large individuals of *Scarus rivulatus* reflects a simple scaling relationship between size of grazing scars and fish body size ($TL^2 \times \text{scar area}$, $TL^3 \times \text{scar volume}$). These relationships suggest a strong linear relationship between fish size and the amount of substratum removed and, thus, that the grazing impact of *S. rivulatus* is highly dependent on its body size. In both cases, the relationship was approximately isometric, suggesting that the changes are directly linked to a change in size rather than developmental state. These same functions were found in an excavating and a scraping species (sensu Bellwood & Choat 1990) in the Caribbean (Bruggemann et al. 1994b). These findings suggest that this may be a general relationship that applies to most scarid species. Thus, grazing by large-bodied scarids in general will probably have a distinctly different impact on the substratum than small conspecifics. Although this relationship must be tested in more species before it can become a valid generalization, it appears that large-bodied scarids may have a particularly strong effect on the benthic structure and that management rules must consider not only species composition, but fish size as well.

A previous study at Orpheus Island showed a gradient in herbivory across reef zones, with both grazing pressure and abundance of large-bodied herbivorous fishes higher at the reef crest (Fox & Bellwood 2007). The same study also found a negative correlation between the estimated impact of herbivorous fishes and macroalgal abundance across the gradient, with the crest presenting the highest herbivorous biomass and the lowest macroalgal cover (Fox & Bellwood 2007). The current study complements these findings, in that it indicates that the gradient in fish herbivory would be even greater had fish size been considered. The inner flat is dominated by small individuals, so that the removal of algal volume is minimal. On the other hand, the crest is highly grazed by large-bodied individuals; thus, the removal of algal volume would be much higher than on the flat. The present study lends further support to the herbivore-induced disturbance model of algal community composition (Steneck & Dethier 1994), which predicts that low grazing intensities would lead to the development of climax communities characterized by slow growing taxa, such as macroalgal species.

The present findings probably apply to most scraping *Scarus* species (sensu Bellwood & Choat 1990), as they possess a relatively uniform morphology and feeding ecology (Bellwood & Choat 1990). Moreover, given the morphological differences within excavating species (e.g. *Bolbometopon* spp., *Chlorurus* spp.), it is probable that this group will exhibit an even greater change in impact with size. Preliminary observations at the study site suggest that the grazing effects of small individuals of scraping and excavating species are similar, but that large-bodied excavators have stronger effects on the substratum than large-bodied scrapers. A comparable pattern was found in the Caribbean for the scraper *Scarus vetula* and the excavator *Sparisoma viride* (Bruggemann et al. 1994b). Thus, for both scrapers and excavators, size may be a critical determinant of ecosystem function.

The relationships presented above suggest that large-bodied parrotfishes may have a more significant role in the effective removal of the EAM than small individuals. Although the impact measured in the current study refers to the direct removal of the EAM, experimental studies suggest that this type of activity will have long-term impacts on the community composition of the benthic substratum (McCook 1999). During reef degradation and phase shifts, coral decline may be facilitated or accompanied by a proliferation of algal turfs (Diaz-Pullido & McCook 2004, McManus & Polsenberg 2004, Birrell et al. 2005, Hughes et al. 2007). This suggests that large individuals of *Scarus rivulatus* may have a more significant role than small individuals in the maintenance of the benthic structure

community of coral reefs and for the prevention of phase shifts in these ecosystems.

As a consequence, it is possible that the resilience of coral reefs, i.e. the capacity of a system to resist or recover from changes, would be primarily due to the presence of large-bodied herbivorous fishes. However, in many parts of the world the numbers of large parrotfish individuals are declining because of overfishing (Bellwood et al. 2003, Graham et al. 2005, Floeter et al. 2006, Mumby et al. 2006), a situation which may lead to phase shifts on coral reefs (Hughes 1994, Hughes et al. 2005, 2007). Given the varying impacts of different sized parrotfishes, it is clear that high fish number or biomass alone cannot be viewed as evidence of an intact ecosystem with fully operational ecosystem functions. The absolute size of individuals may be critical. Thus, when evaluating management options, managers should consider not only the numbers, identity and biomass of the species which might be protected, but also further characteristics, such as individual size and ontogenetic phase.

The functional role of fishes is not a species trait; it depends on the intraspecific variations, in which size is a critical factor. Although intra- and interspecific differences among reef herbivores have been known for a long time (e.g. Lewis & Wainwright 1985, Carpenter 1986, Choat 1991, Floeter et al. 2005), their broader importance has only become evident recently, in the face of reef degradation and expanding threats to coral reefs (Bellwood et al. 2004, Mumby et al. 2006, Hughes et al. 2007). Thus, detailed studies on the functional role of reef species are essential, as they can provide important information about functional redundancy and coral reef resilience. In recognizing the importance of fish size, hopefully we can better understand the impacts of fishing activities and enable managers to formulate effective management strategies to protect coral reefs.
