ABSTRACT: Microbial respiration of particulate organic carbon (POC) is one of the key processes controlling the magnitude of POC export from the surface ocean and its storage on long timescales in the deep. Metabolic processes are a function of temperature, such that warming sea temperatures should increase microbial respiration, potentially reducing POC export. To investigate this in the Southern Ocean, we measured microbial oxygen consumption of large particles over a 10°C temperature range (summer maximum +8°C) to then estimate the decrease in export by 2100. Our results showed that POC-normalised respiration increased with warming. We estimate that POC export (scaled to primary production) could decrease by $17 \pm 7\%$ (SE) by 2100, using projected regional warming (+1.9°C) from the IPCC RCP 8.5 ('business-as-usual' scenario) for our sub-Antarctic site. Increased microbial respiration is one of many processes that will be altered by future climate change, which could all modify carbon storage in the future. Our estimate of the potential decline in carbon sequestration is within previous estimates from lab and field experiments, but higher than simple mechanistic models. To explore our results further, we used the metabolic theory of ecology (MTE) to determine the activation energy of microbial respiration, which was 0.9 eV. This is higher than classical MTE (0.6–0.7 eV), suggesting that sub-Antarctic microbes are particularly sensitive to temperature change. Such regional characteristics in the response of organisms to increased temperatures should be accounted for in large-scale or global model analyses to ensure that the results do not underestimate microbial responses to warming.

INTRODUCTION

The ocean's biological pump transfers 5–15 Gt C yr⁻¹ of particulate organic carbon (POC) from the surface to the deep ocean globally, where it can be stored on long (100s–1000s of years) timescales (Volk & Hoffert 1985, Falkowski et al. 1998). As biogenic particles sink through the water column, they are subjected to intense remineralisation by heterotrophic bacteria and zooplankton (Steinberg et al. 2008, Cavan et al.

2017a). Bacterial respiration (a proxy for remineralisation) integrated over the upper 1000 m is typically 4- to 7-fold higher than zooplankton respiration, as bacteria are present throughout this entire depth range, whereas zooplankton are largely restricted to certain depth strata, typically in the upper mesopelagic (Steinberg et al. 2008, Giering et al. 2014). Particle remineralisation (e.g. respiration) and sinking rates together control the attenuation of POC with depth (Boyd & Trull 2007). Oceanic microbial

(including bacteria and protistan zooplankton) respiration is therefore one of the key regulators in determining the magnitude of POC that is sequestered under present-day ocean conditions.

Temperature exerts important controls on the biological pump (Marsay et al. 2015), as it (1) influences the phytoplankton community composition and thus ballasting of POC export and flux (Francois et al. 2002, Henson et al. 2012), (2) helps set the efficiency of POC export from the surface ocean (Laws et al. 2000, Cael & Follows 2016), (3) determines sinking rates (Bach et al. 2012, Iversen & Ploug 2013) and (4) controls metabolic functions (Boltzmann 1872, Arrhenius 1889) that act to remineralise the POC, such as respiration and grazing rates. Future changes in ocean temperature will affect the magnitude of POC export due to altered rates of particle settling and heterotrophic POC degradation (Iversen & Ploug 2013). In this study, we focussed specifically on the role of temperature on microbial heterotrophic POC respiration. Increased respiration caused by future warming may decrease the export of POC from the surface waters and hence carbon sequestration to the deep oceans and sediments.

Many experimental studies have investigated the effect of warming on marine microbes, mostly bacteria, such as in upper ocean Arctic and temperate mesocosm studies, which have shown increased bacterial respiration, growth rates and biomass with warming (Hoppe et al. 2008, Lara et al. 2013). Deeper in the mesopelagic zone (300–600 m), bacterial respiration and production also increased with temperature (Mazuecos et al. 2015). Such reports of increased microbial activity are either due to the metabolic response of bacteria to warming and/or the enhanced release of dissolved organic carbon (DOC) from phytoplankton at higher temperatures (Hutchins et al. 2017). Nevertheless, the relationship between temperature and metabolic rates is not straightforward in marine microbes, since substrate availability strongly affects their response to changes in temperature (Aguilar-González et al. 2012, Arandia Gorostidi et al. 2017, Maske et al. 2017). Furthermore, a review study using the metabolic theory of ecology (MTE) showed that bacteria and protistan metabolic processes exhibit a different response to changing body mass compared to more evolved organisms (DeLong et al. 2010).

The long-established MTE links metabolic rates to temperature and body size, such that rates of all organisms scale in the same way via the following equation (Arrhenius 1889, West et al. 1997, Gillooly et al. 2001, Brown et al. 2004):

$$\ln(I M^{-0.75}) = -E_a(1/cT) + \ln(i_0) \quad (1)$$

where I is the metabolic rate normalised by biomass (M), E_a is the activation energy, c is Boltzmann's constant ($0.862 \times 10^{-5} \text{ eV K}^{-1}$), T the temperature in Kelvin, and i_0 is a normalisation constant. E_a is the minimum energy needed to result in a chemical reaction (Clarke & Johnston 1999, Yvon-Durocher et al. 2012), and MTE states that all organisms should have an E_a of 0.6–0.7 eV (Gillooly et al. 2001, Brown et al. 2004). An E_a higher than 0.6–0.7 eV suggests that organisms or communities are more sensitive to changes in temperature (Clarke & Johnston 1999), as is the case for mesopelagic bacteria which can exhibit an E_a of 0.9 eV (Mazuecos et al. 2015). In this study, we used MTE to determine the microbial E_a to allow us to make projections on the response of sub-Antarctic microbes to future warming and identify how the metabolism of these microbes subsequently affects the flow of carbon in the upper ocean (Schramski et al. 2015). Whilst relatively simple to apply, MTE is based on fundamental physical and chemical principles to understand and predict fluxes of energy and matter through individuals and ecosystems (Yvon-Durocher et al. 2010a, Schramski et al. 2015). To our knowledge, MTE has not been applied to the biological pump, and thus our study is the first to experimentally apply MTE in the context of sinking organic particles.

Our primary objective was to determine the effect of increasing temperatures on microbial remineralisation of sinking POC, in the context of carbon export and the biological pump and predict these rates for the year 2100. A secondary objective was to identify the temperature sensitivity of sub-Antarctic microbes by calculating the E_a of mass-normalised microbial respiration by applying MTE to our results. We hypothesised that warming will increase microbial respiration, reducing POC export to the mesopelagic. We tested this experimentally by measuring the relationship between microbial oxygen consumption of large, organic, carbon-rich particles and temperature in the sub-Antarctic Southern Ocean (Fig. 1).

MATERIALS AND METHODS

Study site and sampling

Sampling took place at the Southern Ocean Time Series (SOTS) site (46°S , 141°E , Fig. 2a) in the sub-Antarctic southwest of Tasmania (Australia), from 20–26 March 2017 onboard RV 'Investigator' (Table 1).

Fig. 1. Microbial processes during POC remineralisation: disaggregation, solubilization and respiration and proportions of mixed layer POC and DOC. Organisms such as nauplii (red organism) can physically disaggregate POC, increasing the POC surface area allowing bacterial colonisation. Bacteria solubilise POC to DOC, and then respire DOC to dissolved inorganic carbon (DIC), the final process in POC remineralisation. All of these processes require energy contributing to heterotrophic oxygen consumption. POC concentration was 5–35× higher in our vials than *in situ*, such that the substrate (POC) did not become limiting during the incubations. Mixed layer, autotrophic biomass only contributes to 50% of mixed layer POC, the remainder being heterotrophic, with a very small detrital fraction (Furuya 1990, Boyd et al. 1995, Strzepek et al. 2005). Mixed layer DOC is mostly refractory, with a small proportion being semi-labile and a minute fraction being labile (Carlson & Ducklow 1995, Aminot & K erouel 2004). The particle and nauplii images were taken from samples (Net 2) from this study

son & Ducklow 1995, Aminot & K erouel 2004). The particle and nauplii images were taken from samples (Net 2) from this study

The site is within a high-nutrient/low chlorophyll (HNLC) region where microbes are considered particularly important in carbon cycling (Manganelli et al. 2009), as low chlorophyll concentrations and low rates of primary production can reduce grazer abundance. A conductivity-temperature-depth sen-

sor package mounted on a rosette frame was deployed to measure upper ocean properties (Fig. 2b). Mean aqua MODIS chlorophyll *a* (chl *a*) satellite data for the month of March 2017 were used to derive surface chl *a* concentrations at the SOTS site and the surrounding waters (Fig. 2a).

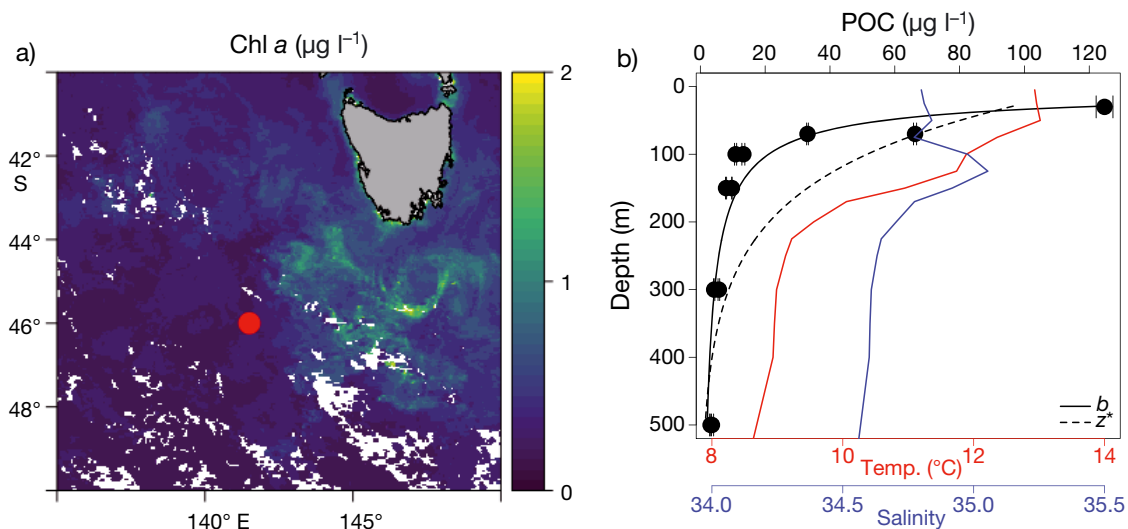

Fig. 2. Water column properties at the Southern Ocean Time Series (SOTS) site. (a) Mean satellite-derived chlorophyll *a* from MODIS satellite data for March 2017. Red dot represents SOTS in relation to Tasmania (grey-shaded land mass). No data (white shading) is due to cloud cover. (b) Temperature (red line), salinity (blue line) and particulate organic carbon (POC) concentration (black lines and symbols, collected using *in situ* pumps) through the upper 500 m at SOTS. Error bars are SEM ($n = 3$). The solid black line is a fitted power function with the exponent b ($p < 0.001$, $r^2 = 0.88$) and the dashed black line is a fitted exponential function with the exponent z^* ($p < 0.01$, $r^2 = 0.63$), both describing the long-term (assuming steady state) attenuation of POC with depth

Table 1. Locations and times of plankton net deployments and the temperature settings of the 3 incubations per net deployment in 2017. Time is given in local time (Australian Eastern Time). See Fig. S1 in the Supplement at www.int-res.com/articles/suppl/a082p111_supp.pdf for an image of the net

Net	Date (dd/mm)	Time (h)	Latitude (°S)	Longitude (°E)	Temp. (°C)
1	21/03	20:30	46.73	141.93	12, 17, 19
2	23/03	18:00	46.60	141.93	12, 16, 21
3	24/03	12:30	46.08	142.29	12, 15, 22
4	25/03	12:00	46.05	142.18	12, 18, 20
5	26/03	10:00	45.92	142.25	12, 14, 15

POC concentration

Six *in situ* pumps (ISPs, McLane) were deployed twice during the voyage at 30, 70, 100, 150, 300 and 500 m to obtain samples for POC analysis. The ISPs were deployed for 2 h with 142 mm diameter QMA-quartz (2.2 µm pore size) filters (pre-combusted, 400°C). Water (200–1000 l) was pumped through the filters depending on the particulate stocks at each depth; hence the volume filtered increased with depth. On return to deck, the large QMA filters were removed, subsampled by punching 3 (replicate) 13 mm holes through each filter. These 3 subsamples were then dried and stored until their return to land. In the laboratory, the dried subsampled 13 mm filters were placed into silver cups (Elemental Microanalysis), and 20 µl of 2NHCl Suprapur were added to each cup. The cups were put in a fuming bell overnight to remove inorganic carbon and then dried at 60°C for 2 d. The cups were pelleted, and C was then analysed on a CHN analyser (Thermo Finnigan EA 1112 Series Flash Elemental Analyser).

Particle collection

To measure microbial oxygen consumption associated with large particles, the particles (the substrate) need to be in high concentration to get a significant signal (del Giorgio 1992, Amon & Benner 1996, Boyd et al. 2015). As the SOTS site is in the HNLC sub-Antarctic waters, particle collection and concentration by conventional methods (such as pre-concentration by settling [Cavan et al. 2017b], or enhancing particle collision in roller tanks [Ploug et al. 2008]) did not produce a high enough particle concentration for oxygen consumption incubations. Therefore, we deployed a plankton net (200 µm mesh, see Fig. S1 in

the Supplement at www.int-res.com/articles/suppl/a082p111_supp.pdf), originally designed to sample under sea ice at discrete depths (Fukuchi et al. 1979). The net consists of a plastic tube with a motor driving a propeller at one end directing particles into a short (1 m length) net with a cod-end attached (Fig. S1). The plankton net was deployed to a depth of 30 m within the surface mixed layer for 10 min on 5 different days during the voyage (Table 1). This sampling resulted in a higher (5–35×) concentration of particles than would be found *in situ* because particle collision, hence aggregation, was enhanced due to lateral movement of water through the net.

Particle incubations for microbial oxygen consumption measurements

The plankton net was rinsed with seawater from the filtered underway system on the vessel to remove particles from the mesh and to capture them in the cod-end. The cod-end was removed and any large (non-microbial, >200 µm) zooplankton ‘swimmers’ were manually picked out of the sample. Here, we classify respiring microbes as all non-visible (<200 µm) heterotrophs, including bacteria and microzooplankton (e.g. copepod nauplii and protists). For every net deployment (5 in total), the sample (including both large particles and the associated and free-living microbial community) was firstly divided into 3 to run parallel incubations at 3 different temperatures. One incubation was always at 12°C, i.e. the control temperature (Table 1) and the ambient sub-Antarctic seawater temperature in March 2017. The other 2 temperatures were set between 14 and 22°C (Table 1), which are above the seasonal temperature range (8–12°C) to which sub-Antarctic microbes are exposed (Trull et al. 2001a).

Even though projected increases in temperature are only 2–3°C in the sub-Antarctic, we exposed microbes to temperatures above this projected warming to (1) determine the slope of the relationship between temperature and respiration and (2) assess their thermal reaction norm (i.e. performance versus environment) (McMeekin et al. 2013, Corkrey et al. 2016). For the 3 incubations (at different temperatures) for each net deployment, the sub-samples were further sub-divided into 3 × 20 ml acid-cleaned borosilicate microrespiration vials (Brandon Scientific Glassblowing) (see Fig. S2 for experimental setup). This resulted in a total of 9 micro-respiration vials per net deployed, 3 in each of the 3 temperature-controlled water baths. Incubations were car-

ried out in the temperature-controlled laboratory (set to 12°C) onboard the RV 'Investigator'.

The microrespiration vials were filled with the sample to the top of the vial, the lid with a small capillary hole was placed onto the chamber, and a final drop of sample was added to the top of the lid to expel all air. The capped vials were then immersed within the baths filled with seawater so there could be no gaseous exchange between the vials and the surrounding water. Temperature in the baths was set by thermostatically controlled heat plates, and the baths were kept in darkness during each 8 h experiment. The microbes were allowed to acclimatise for ~1 h prior to the first oxygen measurement.

Our experiments were run in the dark to prevent photosynthesis and limit DOC release from phytoplankton, which is also light-mediated (Cherrier et al. 2015). Oxygen concentration ($\mu\text{mol l}^{-1}$) was measured in each vial at discrete time intervals (every 2 h) over 8 h using a Presens micro-electrode (limit of detection = 15 ppb, accuracy = 0.05 % O_2). The vials were inverted prior to each oxygen measurement to homogenise the sample. The remainder of the sample (~150 ml) from each net deployment not in the vials was run through a FlowCAM (Álvarez et al. 2011) onboard where images were taken for manual classification of particles and automation of the size (equivalent spherical diameter) of each particle. As the net pore size (200 μm) was greater than the size of most microbial organisms and bacteria, we assumed that most of the respiring microbes would be particle-attached (McDonnell et al. 2015).

Microbial POC turnover

To determine biomass-normalised microbial respiration rates (microbial POC turnover), oxygen consumption rates were computed using linear regression with the `lmList` function in R (Cavan et al. 2017b). Oxygen consumption rates ($\mu\text{mol l}^{-1} \text{h}^{-1}$) were calculated as the slope of the linear regression between oxygen concentration ($\mu\text{mol l}^{-1}$) and time (h). The mean non-significant oxygen consumption rate in this study was $0.48 \mu\text{mol O}_2 \text{l}^{-1} \text{h}^{-1}$, an order of magnitude greater than measured on unconcentrated (unamended) seawater using an ultrasensitive oxygen sensor ($0.085 \mu\text{mol O}_2 \text{l}^{-1} \text{h}^{-1}$) (Tiano et al. 2014). Oxygen consumption rates were those where there was a significant ($p < 0.05$ in linear regression) decrease in oxygen in a vial over 8 h. Data derived from vials with non-significant oxygen consumption rates were removed before carrying on with the

analysis. We made 45 measurements of oxygen consumption, and only 5 were non-significant ($p > 0.05$). At the end of the experiment, the contents of each vial were filtered through a pre-combusted (overnight, 400°C) QMA-quartz filter, dried and then stored at room temperature until subsequent elemental analysis. On return to the laboratory, these QMA filters were prepared and processed for POC analysis as above.

The oxygen consumption rates were converted from $\mu\text{mol l}^{-1} \text{h}^{-1}$ to $\mu\text{mol h}^{-1}$ by multiplying by the volume of the vials (0.02 l), and then the POC mass within each vial was converted from μg to μmol . To compute the POC turnover rate, the oxygen consumption needs to be normalised to the mass of respiring heterotrophs in the vials. We do not have data from the voyage to tease apart the relative proportion of heterotrophs to total POC in the mixed layer, and therefore our vials. POC in the mixed layer is formed of autotrophic, heterotrophic and detrital POC; therefore, the mass of both living autotrophic and detrital POC is needed to determine heterotrophic biomass (Fig. 1).

Here we used data from Strzepek et al. (2005), which represent the state of the art on estimating biotic carbon stocks based on ~8 d occupation of an SF6-labelled patch (~200 km^2) of the HNLC sub-Antarctic ocean at 46° S, i.e. the same latitude as our study site, south of New Zealand in summer. During the study by Strzepek et al. (2005), the various components of the POC pool were assessed on a daily basis within a quasi-Lagrangian framework. The authors showed that throughout the 8 d, heterotrophs consistently formed 50% of the total living POC biomass within the mixed layer (Fig. S3). S. Nodder (unpubl. data) found that total POC in the mixed layer from the same water mass as in Strzepek et al. (2005) was 12 μM . The total living (auto- + heterotrophic) POC measured by Strzepek et al. (2005) was 11.7 μM , showing that the detrital component is negligible in the mixed layer. This was also confirmed in the NE Pacific HNLC region by Boyd et al. (1995). Therefore, we assumed that heterotrophic biomass was 50% of POC mass in the vials and thus divided our POC mass by 2 to compute the non-heterotrophic (autotrophic + detrital) POC turnover by microbial heterotrophs:

$$k \text{ (d}^{-1}\text{)} = \text{oxygen consumption (}\mu\text{mol h}^{-1}\text{)} / \text{(POC mass [}\mu\text{mol]}/2) \times 24 \quad (2)$$

with the turnover rate (k) being expressed as a rate per day, not per hour, to allow comparisons with other studies.

To compute k , we assumed a respiratory quotient of 1 mol O₂ to 1 mol of CO₂ following Trimmer et al. (2012), as in marine habitats the ratio of O₂:CO₂ is ~1.03:1 (Canfield et al. 1993) but can range from 0.8–1.2 (Glud 2008). Two incubations (at 18 and 20°C) produced anomalously high (i.e. +2 SD above the mean) k values of 4.9 and 11 d⁻¹. Both of these were from net deployment 4, so all k values from this sample were removed from subsequent analysis. The control incubation at 12°C of net deployment 4 also resulted in the highest k values for that temperature (mean for net deployment 4 at 12°C = 0.65, mean across all nets at 12°C = 0.40). Microbial communities and activities are largely invariant from day to day in HNLC regions during summer (Strzepek et al. 2005; Fig. S3) and thus we cannot explain the high k values. These high POC turnover results would have further increased the slope between temperature and k , and thus our estimates of future microbial respiration. Removing these data reduced the number of microbial POC turnover rates calculated from 40 to 31.

Rationale for design of the particle incubations

We used short (8 h) incubations to reduce physiological and taxonomic changes in the microbial community during incubations (Pomeroy et al. 1994, Gattuso et al. 2002, Maske et al. 2017). The 8 h incubation time was in line with a previous study on the effect of temperature on bacteria in Chesapeake Bay, USA (Apple et al. 2006). However, had we run the incubations for longer (days to weeks), the response of respiration to temperature would likely be reduced, as the microbial community acclimates and adapts to the different environmental conditions. Thus, our incubation time means we cannot assess any acclimation and/or adaptation by the microbes. However, small organisms have shorter generation times, larger population sizes and higher genetic diversity, making microbes an ideal test subject (Ochman et al. 1999) for our short experiments. Another advantage of a short incubation is that it reduces the time available for wall or bottle effects to influence our results. We also used 20 ml sized vials, which were 5× larger than similar previous studies (Cavan et al. 2017b, Koski et al. 2017), to further reduce bottle and wall effects. However, the vials were still small enough to allow us to concentrate particles into a small volume and measure a decline in oxygen concentration.

The high concentration of POC from large organic particles in our 20 ml vials ensured no substrate limi-

tation, which is important, as metabolic reactions, such as respiration, are and can become substrate limited (Clarke 2006, López-Urrutia 2008, Arandia Gorostidi et al. 2017). During long incubations (days or weeks) if the substrate becomes limiting, a non-linear relationship persists between oxygen concentration and time. In this instance, the linear MTE is not appropriate and an enzyme kinetic model, which accounts for substrate, should be used (Aguilar-González et al. 2012). In addition, high concentrations of substrate are needed to observe a detectable signal of oxygen consumption (Cavan et al. 2017b).

The oxygen consumption measured in the vials would have resulted from the following energy-consuming transformations of POC: heterotrophic mechanical disaggregation to smaller particles (Collins et al. 2015), solubilisation of POC to DOC (Kjørboe & Jackson 2001) and, prior to the final stage of remineralisation, respiration to dissolved inorganic carbon (Fig. 1).

Ecological theory

We did not measure primary production in this study as the experiment was conducted in the dark, but used a published MTE equation for primary production (López-Urrutia et al. 2006) to estimate mass-specific primary production at different temperatures:

$$\ln(k_{pp}) = [-0.29 \times (1/cT)] - 11.28 \quad (3)$$

where k_{pp} is the mass-specific primary production, c is the Boltzmann constant (0.862×10^{-5} eV K⁻¹), and T is temperature in Kelvin. As primary production is a metabolic function, it is also predicted to increase with temperature according to MTE, but to a lesser extent (i.e. the slope for respiration = 0.6–0.7, and the slope for primary production = 0.3). We use k_{pp} to estimate the potential percentage increase in primary production and therefore the overall net effect of increasing temperature on export (change in primary production – change in respiration). When projecting future primary production using multi-model means over many earth system models (ESMs), primary production is projected to decrease globally due to reductions in nutrient concentration and enhanced stratification, even though in almost half of the ESMs, no changes or increases in primary production are actually predicted (Laufkötter et al. 2013). Primary production is projected to increase when temperature-dependent production terms are included in models (Taucher & Oschlies 2011), as also predicted by simple MTE.

Linear models were fitted between temperature and POC turnover. First, a simple linear regression was computed between k values and temperature (Table 2). We then fitted a linear mixed-effect (LME) model using the `lme4` package in R (Bates et al. 2015), where the random effect was the time of sampling (hour of day, Table 1) and the fixed effect was the temperature of the incubations (Table 1). The projected temperature change by 2100 specifically at the SOTS site was isolated from global IPCC representative concentration pathway (RCP) 8.5 ('business-as-usual') multi-model median temperature change data output from CMIP5 models, as in Henson et al. (2017). The estimated change in respiration is calculated using the linear models. As such, the error associated with this estimate is given as a range, as it is calculated by adding the standard error to, and then subtracting it from, the 2 coefficients (slope and intercept) in the linear models to estimate the minimum and maximum (respectively) change in respiration.

Both the linear and LME statistical models are standard Model I regressions, which assume no error in the independent x variable. Use of the Model I regression is justified in this analysis, as temperature was kept constant and controlled by the experimental design. If both variables are random and not controlled by the researcher, then a Model II type regression that assumes error in both variables is required (Laws & Archie 1981, Legendre & Legendre 1998). A Model II regression should always be used under these circumstances, although in biological oceanography, Model I regression is most commonly used. Using a Model II regression in our study would not change the significance of the model fit nor the r^2 , but it would change the slope, such that if the model was used to project microbial respiration at higher temperatures, the projected change would be different and either be an under- or an over-estimate.

Table 2. Model selection and statistics for linear and linear mixed effect (LME) models used to assess the response of k (microbial particulate organic carbon turnover) to temperature. T : temperature the experiment was run at, $time$: sampling time that particles were collected from the mixed layer (Table 1), AIC: Akaike's information criterion, SE: standard error of the fixed effect (temperature)

Model	Model structure	p	AIC	SE
Linear	$\log(k) \sim T$	<0.01	60.5	0.031
LME	$\log(k) \sim T + (1 time)$	<0.01	54.2	0.026

RESULTS

At the SOTS site in March 2017, surface chl a concentrations were low ($0.23 \mu\text{g l}^{-1}$, Fig. 2a) as expected for an HNLC region. Mixed layer (30 m) POC concentration was $>120 \mu\text{g l}^{-1}$ and rapidly declined in the mesopelagic zone (base of the mixed layer, to 500 m; Fig. 2b) to $<5 \mu\text{g l}^{-1}$. Particles derived from the 200 μm mesh plankton net at 30 m were dominated by diatoms (Fig. S5), particularly the genera *Rhizosolenia* sp. The natural mixed heterotroph community contributing to oxygen consumption consisted of free-living and particle-attached nauplii, pteropods, foraminiferans, small copepods (as identified from FlowCAM images) and bacteria. Particle size ranged from 200–2500 μm in equivalent spherical diameter (ESD), with a mean ESD of $364 (\pm 2 \text{ SE}) \mu\text{m}$. The mean ESDs for each net deployment were similar (60 μm difference, or 15%), ranging from a low of 349 μm in Net 3 to a high of 407 μm in Net 5. Small (200–400 μm ESD) particles dominated (67%) the incubations in this study (see Fig. S6). The attenuation of particles, or here POC concentration with depth (Fig. 2b), can be described either using a power law function such as the b value, which in this study was 0.70 ($p < 0.001$, $r^2 = 0.88$) (Martin et al. 1987) or an exponential function using the exponent z^* (depth by which 63% of the POC has been remineralised), which was 114 m ($p < 0.01$, $r^2 = 0.63$) (Boyd & Trull 2007).

In our incubation studies, the POC concentrations in the vials were very high ($0.6\text{--}4.2 \text{ mg l}^{-1}$), i.e. 5–35 \times higher than at 30 m *in situ* (Fig. 2b). Combining this high concentration and short incubation time ensured that the substrate did not become limiting. Thus, oxygen concentration declined with time in all vials over the 8 h experiments (Fig. 3a). The mean oxygen consumption for all temperatures was $3.3 \pm 0.3 \mu\text{mol O}_2 \text{ l}^{-1} \text{ h}^{-1}$. Significant ($p < 0.05$) changes in oxygen concentration were observed at the lowest (control) temperature (12.0°C), most similar to that *in situ* (13.0°C in the mixed layer) over all of the 8 h incubations. As temperature increased, oxygen consumption and POC turnover rates (k) also increased (Figs. 3 & 4) but not always in a uniformly linear manner; k increased up to 15°C , then decreased up to 17°C , before increasing again to reach the maximum k at the maximum temperature of 22°C (Fig. 3b).

The mean POC turnover (k) normalised to heterotrophic biomass at the control temperature was $0.97 \pm 0.10 \text{ d}^{-1}$. The total range of POC turnover measured in this study was $0.33\text{--}5.25 \text{ d}^{-1}$, from the lowest (12°C) and highest (22°C) temperature incubations, respectively (Fig. 4a). Time of day had a significant

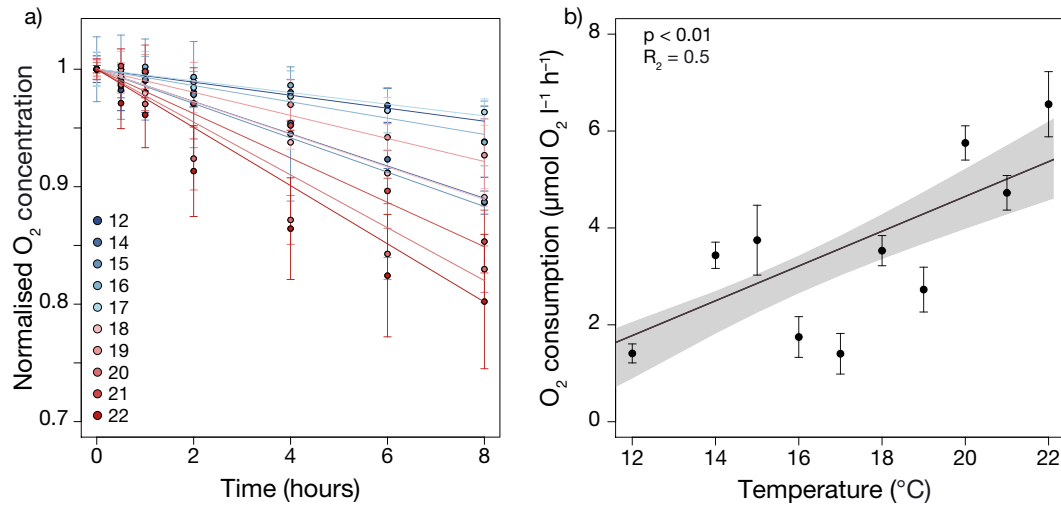

Fig. 3. (a) Normalised oxygen concentration (unitless) over the 8 h incubations. Different coloured lines represent different incubation temperatures (°C). The oxygen consumption has been normalised (to 1) to show the relative decline in oxygen at different temperatures during the incubations over the 8 h period. (b) Mean oxygen consumption at each temperature prior to normalising for the particulate organic carbon concentration. Grey area shows 95% confidence intervals. This plot can be interpreted to show the reaction norm of microbes over a range of temperatures and that the maximum temperature for microbial oxygen consumption cannot be determined from this study and hence is likely 22°C or higher. In both plots, error bars are SEM, and $n = 3$ for all temperatures apart from at 12°C, where $n = 15$ and 15°C where $n = 6$ at each time point

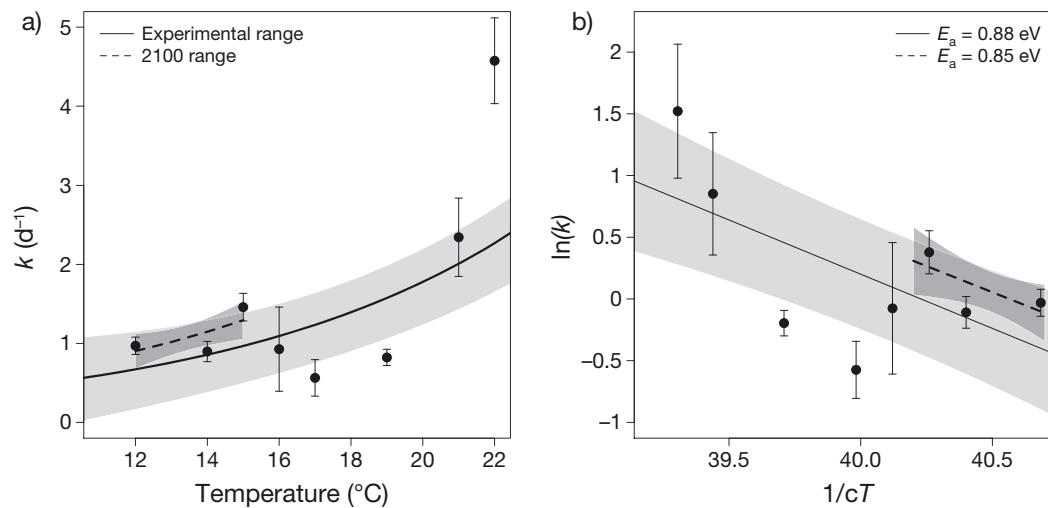

Fig. 4. Particulate organic carbon (POC) turnover (k) against temperature with linear regressions for respiration produced by mixed-effect modelling. k values for respiration (O_2 uptake was divided by heterotrophic biomass) are shown by the closed points, with the linear mixed effect (LME) model denoted by the solid line over the full experimental temperature range. The dashed line is the LME model from our control temperature to the projected temperature at SOTS in 2100. (a) POC turnover (k) with temperature (°C) where for the experimental range (solid line), $r^2 = 0.45$ ($p < 0.01$) and for the 2100 range (dashed line), $r^2 = 0.49$ ($p < 0.01$). (b) Classic metabolic theory of ecology (Arrhenius) plot where c is the Boltzmann constant (0.862×10^{-5} eV K^{-1}), T is temperature in Kelvin, and the natural log of k is shown. The LME model line for the experimental range (solid line) has an $r^2 = 0.40$ ($p < 0.01$) and for the 2100 range (dashed line), $r^2 = 0.41$ ($p < 0.01$). The slope of both lines, which is the activation energy (E_a) in (b), is -0.9 eV (0.88 and 0.85 eV to 3 significant figures, respectively). Grey areas show 95% confidence intervals

but minor effect on oxygen consumption ($p < 0.01$, $r^2 = 0.15$), so the LME model improved the model fits with lower error and lower Akaike's information criterion (AIC) compared to the linear regression (Table 2). Hence the LME models are presented here (see Fig. S4 for comparisons between the linear and

LME models) and are used in our projections of respiration with increased temperature:

$$R = e^{([0.12 \times \text{Temp}] - 1.9)} \quad (4)$$

where Eq. (4) is the regression from the LME model in Fig. 4a, of POC turnover against temperature (°C)

across the whole experimental range of temperatures used. This regression was used to project the future change in POC turnover with temperature. We also fitted linear and LME models to an Arrhenius plot (MTE) to determine the activation energy where:

$$\ln(IM^{-1}) = -E_a(1/cT) + \ln(i_0) \quad (5)$$

such that IM^{-1} gives the k values and $-E_a$ the activation energy (slope between k and $1/cT$, see Eq. 6):

$$\ln(R_{\text{MTE}}) = (-0.9 \times \text{Temp}) - 35 \quad (6)$$

Eq. (6) is the regression from the LME model in Fig. 4b, of the natural log of k against temperature in Kelvin. The slope of the regression is the E_a . In the LME model, the E_a was 0.9 ± 0.2 eV, much higher than is generally considered in MTE for all organisms (0.6–0.7 eV) (Brown et al. 2004).

When calculating the slope between POC mass and oxygen consumption, a Model II regression was used, as the POC mass was not controlled and so is considered a random variable. We presented POC mass against oxygen consumption with both type Model I and Model II to highlight the large difference in slope given by these 2 models (Fig. S7). Neither model significantly fitted these data.

DISCUSSION

Respiration is one of the key metabolic processes driving the remineralisation of organic carbon in the oceans (del Giorgio & Duarte 2002). This process is closely linked to temperature (Brown et al. 2004), hence climatic-driven changes in ocean temperature will directly influence the extent of POC remineralisation and ocean carbon storage (Iversen & Ploug 2013). We directly measured oxygen consumption by microbial organisms (Fig. 1), with unfiltered large, organic carbon-rich particles the main supplied substrate for the microbes. We investigated the effect of increasing water temperature on microbial remineralisation of large particles in the sub-Antarctic Southern Ocean.

The upper ocean at the SOTS site is representative of conditions for a large proportion of the Indian and Australian sectors of the sub-Antarctic Southern Ocean (Trull et al. 2001b). The SOTS site is within the sub-Antarctic HNLC region, so chl a concentrations are low throughout the year (Bowie et al. 2011, Ebersbach et al. 2011, Eriksen et al. 2018), as we observed during our study. In addition, silicate concentrations are seasonally low ($<2 \mu\text{mol kg}^{-1}$ in summer), compared to the more southern polar frontal zone

and other HNLC areas (Rintoul & Trull 2001, Trull et al. 2001c). Hence SOTS in summer is best described as a high nutrient, low silicate, low chl a region, as also observed in the equatorial Pacific, where picoplankton are responsible for most of the primary production and diatoms for new production (Dugdale & Wilkerson 1998). At SOTS, picoplankton and flagellates are the most abundant phytoplankton, but dino-flagellates dominate the phytoplankton carbon biomass (Kopczynska et al. 2001). Small-sized plankton communities result in different particle aggregation pathways and the dominance of smaller exported particles (Cavan et al. 2018) as we observed here (200–400 μm ESD), which is a common characteristic of particles at 150 m at SOTS (Ebersbach et al. 2011). The mesh size of the net (200 μm) constrained the minimum size of the particles. Hence, even though we purposefully had to increase the concentration of larger particles, such pre-concentration did not appear to alter the natural particle size distribution observed at SOTS. Our particle size distribution was well within the size range of large, fast-sinking particles commonly observed elsewhere, such as in the Mediterranean and Equatorial Pacific (Alonso-Gonzalez et al. 2010, Cavan et al. 2017b).

The POC mass of the particles was not proportional to the oxygen consumption rates in each vial as stated by MTE (Fig. S7). The lack of model fit is most likely because both substrate and microbes were in the incubation vials (Fig. 1). This issue could be a factor potentially hindering studies on microbial organisms and MTE, particularly of mixed, natural communities. Additionally, during our incubations some of the oxygen consumption would have been associated with autotrophic respiration, as the phytoplankton were viable at the onset of the incubations. However, the experiments were run in the dark, and studies have shown that heterotrophic respiration is 2–3 times greater than autotrophic respiration (Schindlbacher et al. 2009, Savage et al. 2013).

Effect of temperature on microbial respiration

Seasonal temperatures at SOTS range between 8 and 12°C (Trull et al. 2001a). We sampled at the end of austral summer in March, when the plankton community is exposed to the highest temperatures (Shadwick et al. 2015), but also towards the end of the plankton growing season. Therefore, our selected temperature range (14–22°C) used in the incubations is well above the natural seasonal amplitude that resident flora and fauna encounter at SOTS. However,

our findings from the 8 h incubations demonstrate that the selected temperatures capture the natural temperature range that resident sub-Antarctic microbes can successfully metabolise within (Figs. 4 & 5). For example, the optimum temperature for growth rates of heterotrophic microbes that normally reside at 4–5°C in the Southern Ocean can be up to 18°C (Simon et al. 1999). This is a common phenomenon, and many microbes living in colder waters reside at temperatures lower than their metabolic optimum (Delille & Perret 1989, Pomeroy & Wiebe 2001). In this study, the maximum oxygen consumption rate occurred at the maximum temperature microbes were exposed to (22°C) (Figs. 3b, 4 & 5), with no evidence of oxygen consumption plateauing, suggesting that the optimum temperature for this natural population of sub-Antarctic microbes was 22°C or higher. A similar result was observed during short (6–8 h) incubations of coastal, temperate, marine bacteria in Chesapeake Bay (USA), where the bacterial respiration was highest at the maximum *in*

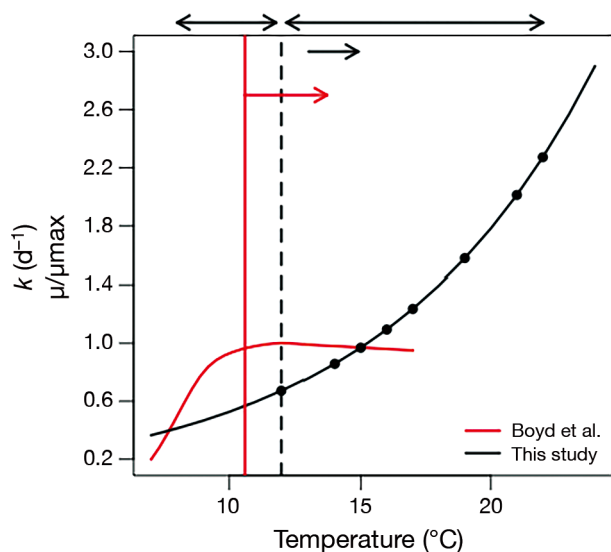

Fig. 5. Reaction norms (fitness versus environment) for sub-Antarctic microbes from environmental manipulation studies. Comparison of the reaction norm of respiration from this study (expressed as particulate organic carbon [POC] turnover, k , per day, black symbols and lines), using the regression from Fig. 4a, and of growth rate versus temperature (red line) of a sub-Antarctic diatom from Boyd et al. (2016). Both reaction norms are on the same scale (y -axis). The vertical lines show the control temperatures, and the arrows show the IPCC-projected increase in temperature at the location of each study (black = Southern Ocean Time Series [SOTS], red = Boyd et al. 2016). The double-headed black arrows show the present-day temperature range at SOTS and the experimental temperature range (black symbols) to which microbes were exposed in this study. The optimum temperature for microbial oxygen consumption cannot be determined from this study and hence is 22°C or higher

situ temperature of 30°C (Apple et al. 2006). We assume heterotrophic microbes were responsible for driving our observed trend between POC turnover and temperature, as autotrophic respiration has a much weaker temperature dependence than heterotrophic respiration (López-Urrutia et al. 2006).

In our study, the time of day for sampling (i.e. net deployment) significantly influenced the subsequent turnover of POC by microbes in the incubations. This could have been due to the short generation times of microbes, particularly prokaryotes (<2 d; Krupke et al. 2016), as their abundance (cell division) and community composition can change due to shifts in the daily primary production cycle and may decrease when light levels are lower because of substrate availability (Ottesen et al. 2014, Aylward et al. 2017). In our study, oxygen consumption during the incubation was normalised by the POC mass in the vial to compute k , such that any difference(s) in microbial and/or substrate concentrations within the vials, due to temporal variability (time of day particles were collected), should not influence the effect of temperature on k . However, there was an effect of time of sampling on the relationship between k and temperature, so changes in microbial community composition, rather than abundance, are likely the important driving factor for the effect of time of sampling on POC turnover rates. In the future, field experiments should be carried out whenever possible at the same time of day and combined with quantifiable enumeration (e.g. flow cytometry and fluorescent staining) of microbial organisms.

At the control temperature of 12°C, our mean POC turnover rates (1 d^{-1}) were higher than the expected range ($0.01\text{--}0.5 \text{ d}^{-1}$) for large particles as determined by both laboratory and open ocean studies (Ploug & Grossart 2000, Iversen & Ploug 2010, Collins et al. 2015, Belcher et al. 2016, Cavan et al. 2017b). However, in these published studies, POC turnover was normalised to total POC mass, not the respiring heterotroph mass. The mean k at 12°C if we just normalise oxygen consumption rates by total POC mass was 0.35 d^{-1} . In addition, above 20°C, $k > 1 \text{ d}^{-1}$, implying the POC in the vials would be completely respired in 1 d. High k values have also been observed at similar temperatures in the equatorial Pacific for small, slow-sinking particles (Cavan et al. 2017b). The particles in our study were small in comparison to other investigations of POC turnover, where particles are typically greater than 1 mm (Iversen & Ploug 2010, 2013), and yield a lower POC turnover ($\sim 0.1 \text{ d}^{-1}$) than we observed. In our study between 12 and 17°C, there was no significant ($p > 0.05$, linear

and LME model) effect of temperature on POC turnover due to the low POC turnover rates at 16–17°C, although it did increase significantly between 12 and 15°C (Fig. 4a), with 15°C being the projected temperature at SOTS in 2100. Previous studies have also shown that the relationship between respiration or production and temperature is constant over lower or intermediate temperatures, but increases when temperatures rise above 22°C (Maske et al. 2017) or 24°C (Regaudie de Gioux & Duarte 2012). In these instances, the metabolic rates at the higher temperatures drove the observed trend. Increased temperature resolution during incubations are needed, along with many replicates, to investigate the relevance of high temperatures driving trends.

Projected change in POC export by 2100

The sub-Antarctic Pacific at the SOTS site is projected to warm by 1.9°C by 2100 under RCP 8.5 (IPCC 2014). Therefore, to estimate potential future changes in respiration we used the LME model (Fig. 4a) to calculate k at 13.0°C (mixed layer temperature in March 2017, Fig. 2b) and at 14.9°C (1.9°C above *in situ* temperature of 13.0°C). Warming of 1.9°C will increase POC turnover by 26% (standard error = 7%) in SOTS models (Fig. 4a). Based solely on theory, using an E_a of 0.29 eV, we estimated that over the same temperature increase, primary production will also increase, but to a lesser extent, i.e. 9% (López-Urrutia et al. 2006). Accounting for this increase in primary production results in a net (change in primary production – change in respiration) increase in respiration (thus potential decrease in export) of approximately 17% ($9 - 26 = -17\%$).

Our calculation of reduced POC export is well within the reported ranges of the estimated decline in carbon sequestration by 2100, including a 4–27% decrease in lake sediments (Gudas et al. 2010) and a 21% (López-Urrutia et al. 2006) or 11% (Yvon-Durocher et al. 2010b) decrease in the surface ocean depending on the E_a used for primary production (0.29 or 0.41 eV, respectively). However, our projected change by 2100 (in 80 yr) is much higher than suggested by a model of recent (1982–2014, 32 yr range) historic changes in the proportion of primary production exported across the base of the euphotic zone (decrease in ~1%), over a similar temperature range in the sub-Antarctic (Cael et al. 2017). Their model was also principally based on thermodynamic theory (Cael & Follows 2016), so one would expect their results to more closely resemble those from this

study. Differences in the magnitude of POC export decline may exist because the respiration in the model of Cael et al. (2017) was constrained by the response of copepod grazing rates to temperature (Huntley & Lopez 1992), whereas ours focussed on a wider range of microbial organisms. Furthermore, the differences between the 2 studies could also have been caused by the impact of the higher temperatures on POC turnover or aspects of our experimental design such as the short incubation times. However, the large dissimilarities in the approaches used between the Cael et al. (2017) historical modelling study and our experimental field study makes it futile to conclude on the differences observed. It does show that more studies are needed, both experimental and using models, to investigate the role of temperature on metabolism and the biological pump.

In our study we have shown that the predicted net change in the turnover of POC by 2100 is a net decrease due to increased microbial respiration. It was beyond the scope of this study to separately test the response of each process in the steps towards remineralisation (disaggregation, solubilisation and respiration, Fig. 1) and temperature. We assume that enzyme solubilisation and the release of DOC also increased with temperature as indicated by microbial remineralisation experiments in marine sediments, where both processes increased up to 27°C (Weston & Joye 2005). We used large, carbon-rich particles as the main introduced substrate in our incubations to simulate particles prior to downward export from the mixed layer, as export occurs when large particles form and their density is greater than the surrounding water (Fowler & Knauer 1986). During aggregation, export and subsequent sinking heterotrophs reduce POC through consumption and solubilisation, but this is most pronounced in the upper ocean, where export commences (Martin et al. 1987). Thus temperature-dependent increases in these heterotrophic metabolic processes due to warming will decrease the amount of available POC for export and subsequent sequestration.

Our results suggest that the amount of POC leaving the upper ocean could be reduced, potentially by almost 20%, decreasing ocean carbon storage and in time altering nutrient concentrations in the deep oceans. Microbial transformations of POC are only one of the many processes that will be altered in the coming decades (Boyd 2015). Other factors that influence particle export are likely to be influenced by warming: any change in both phytoplankton (Thomas et al. 2012) and grazer (Richardson 2008) community composition will affect particle type, size and remin-

eralisation; changes in the viscosity of water may influence particle sinking rates (Iversen & Ploug 2013); and freshening and warming may affect stratification intensity and the supply of nutrients to the mixed layer affecting primary production (Boyd 2015). These plus other physico-chemical and ecological processes will interact with each other to dampen or increase the effects of future global change on the biological pump (Boyd & Brown 2015), and these interactions should be studied at the experimental level.

Assessing the temperature sensitivity of Southern Ocean microbes

Using MTE (Fig. 4b), we can calculate the activation energy (E_a) which characterises the temperature sensitivity of community respiration. Using the LME model, we calculated a higher E_a (0.9 eV) than suggested by MTE (0.6–0.7 eV) (Gillooly et al. 2001, Brown et al. 2004). This E_a of 0.9 eV from our study is the same as determined from mesopelagic (300–600 m) bacterial respiration (0.9 eV) in the South Atlantic and Indian Oceans over a slightly lower temperature range of 9–15°C (Mazuecos et al. 2015). The Q_{10} (proportional increase in respiration per 10°C rise in temperature), which is also a measure of temperature sensitivity, in this study was 3.9 at 15°C using the LME model. These Q_{10} values are also higher than the global (terrestrial and aquatic) average Q_{10} for respiration at 15°C of 2.5 ($E_a = 0.62$) (Yvon-Durocher et al. 2012), but approximate subsurface (>100 m) estimates at 3.6 (Mazuecos et al. 2015, Brewer & Peltzer 2016). The higher E_a and Q_{10} observed here compared to classic MTE shows the higher sensitivity (Clarke & Johnston 1999) of microbial organisms to temperature in the Southern Ocean.

We also ran a sensitivity analysis to test for the effect of normalising all of our k values by 50%, which accounted for the heterotrophic biomass within the vials in accordance with data from Strzepek et al. (2005). To do this, we assigned each k value a random number between 46 and 56% (the range of the proportion of POC mass associated with heterotrophs in the study by Strzepek et al. 2005) and recalculated the slope between the natural log of k and temperature. We repeated this 1000 times, resulting in a mean slope (E_a) of 0.88 ± 0.001 eV, identical to our E_a of 0.9 eV (0.88 to 3 significant figures, Fig. 4b) over the 10°C temperature range. We also repeated this for a larger range in heterotrophic biomass (40–60% of total POC), which yielded a mean E_a of 0.87 ± 0.002 eV (Fig. S8). We therefore conclude that the use of a

constant proportion of POC mass associated with heterotrophic biomass (50%) in all vials does not significantly affect the E_a .

It is not possible from our results to discern whether the high temperature sensitivity is a microbial, Southern Ocean, or a joint microbial–Southern Ocean feature; i.e. do all microbes globally have a higher sensitivity to temperature than metazoans? Are all Southern Ocean organisms cold-adapted? Or is this trend applicable only for Southern Ocean (or polar) microbes? Whilst MTE has been applied to microbes such as phytoplankton and bacteria, the metabolic activity most commonly measured is production (either as growth rates or bacterial production) and of single species or groups, so there are few equivalent studies to compare our results to. Searching the literature, we did find different marine studies that had resulted in identical or similar E_a values, with phytoplankton production and respiration across geothermally heated streams (5–50°C) (Padfield et al. 2017), total oxygen consumption from all organisms in the subtropical mesopelagic (>100 m) (Brewer & Peltzer 2016) and bacterial respiration in the mesopelagic (300–600 m) resulting in E_a values of 0.9 eV. Additionally, a literature study of marine, terrestrial and freshwater habitats identified herbivores, fungi and invertebrates to have the highest E_a of all taxa of >0.7 eV (Dell et al. 2011). Conversely, the latter study also found unicellular organisms such as phytoplankton and bacteria to have much lower E_a at <0.5 eV (Dell et al. 2011).

Most published E_a values are much lower than the results from this study, including from microbial ecosystem respiration in heated ponds (0.62 eV; Yvon-Durocher et al. 2010b), epipelagic bacterial production (0.58 eV; López-Urrutia & Morán 2007), zooplankton grazing (0.67 eV; Chen et al. 2012), oxygen consumption of fish (0.46 eV; Killen et al. 2010) and also specifically reef fish (0.5 eV; Barneche et al. 2014). Nevertheless, a polar (both Arctic and Antarctic) study observed that the respiration of zooplankton resulted in a higher E_a of 1.3 eV (Gleiber et al. 2016), suggesting that these organisms are also more sensitive to temperature change. As we have shown, there is a wide range of E_a values associated with microbial metabolism, and thus our result of 0.9 eV likely represents the cold-adaptation of the resident microbial community to the lower temperatures of this sub-Antarctic region. In addition, our results are most similar to those from the mesopelagic zone (Mazuecos et al. 2015, Brewer & Peltzer 2016), suggesting that species inhabiting cooler, deeper waters are also highly sensitive to temperature changes. Regional or depth-dependent differences in the

responses of organisms to rising temperatures should be accounted for in large-scale or global model analyses to ensure that results do not underestimate their metabolic response to temperature change. Thermal sensitivity could explain why our projected change in export of 17% is much higher than that estimated by Cael et al. (2017) (~1%) over a similar (2°C) temperature gradient. In their study, Cael et al. (2017) used the same model globally, thus not compensating for the different thermal sensitivities of organisms in different biogeographical provinces.

Decreasing the E_a to 0.69 eV ($Q_{10} = 3.3$ at 15°C) in our study in line with MTE (Brown et al. 2004) results in an increase in respiration of just 2%. This small decrease may result in net increases in export if the magnitude of the increase in primary production is greater than 2%. Increases in export have been predicted elsewhere for the Southern Ocean, such as when using ESMs that are not coupled to biogeochemistry models (Britten & Primeau 2016) or in more southerly regions (Cael et al. 2017). The Southern Ocean is a complex and unique environment due to the apparent inverse relationship between primary production and export (Maiti et al. 2013, Cavan et al. 2015, Le Moigne et al. 2016) and the possible 'cold-adaptation' of organisms (Clarke & Johnston 1999). The concept of increased respiration with temperature is by no means novel, but using large, organic particles to mimic the onset of export in the mixed layer and a diverse, natural microbial community is a novel application of MTE.

Relevance of MTE in the context of ocean biogeochemistry

MTE can be thought of as a mechanistic model based on thermodynamics of organisms, which differs from conventional statistical models (e.g. simple exponential or power-law functions) (West et al. 1997). However, MTE assumes that metabolic activity is based solely on supply (temperature), whereas in reality, it is also based on demand (amount of ATP needed for energy) (Clarke 2006) and the amount of available substrate (Aguilar-González et al. 2012, Maske et al. 2017). Additionally, MTE is a linear model such that metabolic functions will continue to increase with increasing temperature, never reaching an optimum which we know is true in nature. In this study, an optimum temperature was never reached (Fig. 5), rendering MTE suitable.

We chose to interpret some of our findings using MTE as it is valuable to ecologists to interpret differ-

ences from the 'null' MTE model (Harte 2004), as we have observed here by the higher E_a . Although MTE has been applied to marine bacteria, rarely is it applied to mixed communities and other non-prokaryotic microbes. Perhaps this is because it is not possible to obtain metabolic resting (non-moving) rates from microbes, which are more useful in MTE at least when comparing between species (Clarke 2017), and it is more difficult to calculate the mass of the respiring organisms separately from the substrate if using field samples as in this study. More studies are needed on the effect of temperature on microbes to elucidate if a higher E_a is due to the typically cold temperatures of the Southern Ocean and/or a global phenomenon of the physiology of microbes. Additionally, designing multi-variable experiments (Boyd et al. 2018) relevant to the biological carbon pump to account for interactions amongst physico-chemical and ecological processes will more closely replicate the natural world (Hutchins et al. 2017).

CONCLUSIONS

Remineralisation of POC in the biological pump is partly controlled by the respiration of microbial organisms. As expected, we found that microbial respiration of large organic particles increases with temperature, and future warming scenarios could decrease export into the mesopelagic zone by 17%. This potential decrease means that more carbon will remain in the upper ocean and in contact over an annual cycle to the atmosphere, decreasing ocean carbon storage in the deep. Using the MTE, we found the Southern Ocean microbial community to be particularly sensitive to temperature changes. Our study suggests that Southern Ocean microbes could have an optimal temperature for respiration above ambient temperatures projected by warming by the end of the century, based on results from our short incubations. MTE has been heavily applied to vertebrates, invertebrates and even marine bacteria, but few, if any, studies have applied it using a natural, mixed community of microbial heterotrophs and linked this to the biological pump. There is a great need for more complex experimental studies on the effects of warming on microbial and larger grazer communities to truly start to predict the change in export production. Of equal importance is the need to account for regional differences in the response of organisms to rising temperatures during large-scale or global model analyses, to ensure results do not underestimate their metabolic response to temperature change.
