**ABSTRACT:** Infection by the protistan *Marteilia refringens* affects the digestive glands of cultured mussels in Galicia, Spain. Effects of the infection on the reproduction of the mussel were studied at 3 sites. Gonad cycle of mussels involved gametogenesis utilizing stored reserves and leading to spring spawning (conservative strategy). This was followed by various sequences of gonad restoration and spawning utilizing the energy from concurrent feeding directly (opportunistic strategy). *M. refringens* significantly inhibited gonad development in the periods of opportunistic reproductive strategy, proportionally to infection intensity. However, the inhibitory effect was not significant in the period of conservative strategy, probably because mussels had developed storage tissue before the infection progressed. Development of storage tissue was estimated by the abundance of adipogranular (ADG) cells in the mantle. Infection by *M. refringens* was clearly associated with inhibition of ADG cell development. The heavier the infection, the lower the abundance of ADG cells. Differences in abundance of ADG cells among categories of mussels with different infection intensity were significant at every site. No significant difference in susceptibility to progression of infection was detected between males and females and a similar mortality rate between sexes can be assumed. Evidence suggests that stress following spawning could enhance the progression of the infection.

## INTRODUCTION

Studies on the effects of parasitic infection on bivalve molluscs, other than causing mortalities, are scarce (reviewed by Newell & Barber 1988) although sublethal effects, such as impairment of gametogenesis, can also disturb host population dynamics. Castration of bivalves as a result of gonad destruction by trematod parasites is well documented (reviewed by Lauckner 1983). Impairment of gonad development can also be caused by interference by parasites in energy acquisition, storage and conversion cycles of the host (Ford et al. 1990). Effects of parasites on gametogenesis of bivalve hosts have been reported (Barber et al. 1988a, Ford & Figueras 1988, Robert et al. 1991).

More than 150 000 t of mussels *Mytilus galloprovincialis* are produced annually in the bays of Galicia, Spain, by suspended culture (Pérez Camacho et al. 1991). Mass raft-culture of mussels markedly determines the ecosystem of these bays, which was dramatically changed after the introduction of mussel culture (Tenore et al. 1982). An infection caused by the protistan *Marteilia refringens* (Paramyxia) affects cultured mussels. Early stages of the infection are located in the stomach epithelium of the host and spreads through epithelia of digestive diverticula, where sporulation of the parasite takes place. Its pattern of progression, prevalence, geographic distribution and association with mortality have been reported elsewhere (Villalba et al. 1993). This paper deals with the effects of the infection on the reproduction of cultured mussels. The

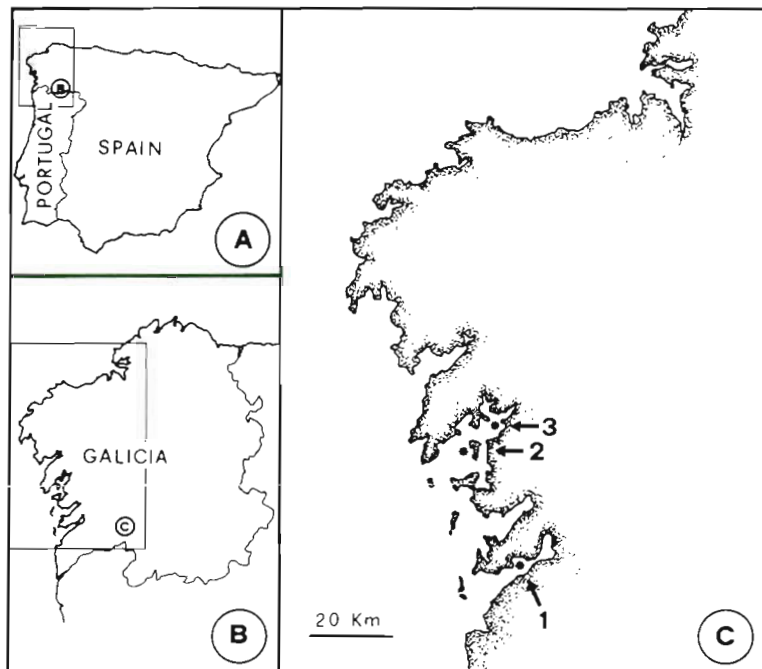

Fig. 1. Location of experimental cultures (\*) in bays off Galicia, Spain. Site 1 is located in Vigo Bay; Sites 2 & 3 in Arousa Bay

objectives of this study were to determine whether infection by *M. refringens* has any influence on gonad development and energy storage, whether females and males show different susceptibility to the infection, and whether postspawning stress enhances the progression of the infection.

## MATERIALS AND METHODS

### Experimental cultures and sampling of mussels.

Experimental cultures used for this study were described in a previous paper (Villalba et al. 1993). Three culture sites (1, 2 & 3) that showed higher prevalences of *Marteilia refringens* (op. cit.) were used for this study (Fig. 1). Cultures were started in February 1988 by tying mussel seed (2 cm long) on ropes hung from floating rafts at Sites 2 & 3. After 6 mo, the culture ropes were thinned and mussels were transferred onto new ropes. Experimental culture at Site 1 began with the thinning-out process, in September 1988. Cultures were terminated when market size (7 cm long) was exceeded, in August and September 1989.

Samples of 30 mussels were taken monthly from each experimental site. An approximately 5 mm thick section of tissue containing gill, visceral mass and mantle lobes was excised from every sampled specimen, fixed in Davidson's solution and embedded in paraffin; 6  $\mu$ m thick sections were stained with Harris' hematoxylin and eosin and examined under light

microscopy for disease diagnosis and analysis of gonad condition.

**Rating of infection intensity.** Each sampled mussel was rated according to the degree of infection, using a scale based on the intensity of infection (Villalba et al. 1993): no infection (NI), when no parasite was detected; light infection (LI), when the parasites were confined to the stomach epithelium or reached primary ducts at most; moderate infection (MI), when a few digestive tubules were infected; and heavy infection (HI), when infection had spread through the digestive diverticula (more than 10% of the digestive tubules visible in a histological section).

**Rating of gonad development.** Morphological condition of the gonad was classified according to the scheme proposed by Lubet (1959): stage 0, resting stage; stage I, multiplication of gonidia; stage II, progression of gametogenesis; stage III A, ripe gonad; stage III B, spawned gonad; stage III C, restoring stage; and stage III D, re-absorbing stage.

**Rating of storage tissue development.** Two types of storage cells occur in the mantle of mussels: vesicular cells and adipogranular (ADG) cells (Bayne et al. 1982). Abundance of ADG cells was used in this study as an index of the level of stored reserves. Abundance was quantified using a scale ranging from 0, when no ADG cell was found, to 5, for the maximum degree of abundance.

**Statistical analysis.** Differences in gonad development, ADG cell abundance, and sex among mussels with different infection intensities were analyzed by G-tests of independence with contingency tables (Sokal & Rohlf 1981). Table columns were the numbers of mussels in each category of gonad condition, abundance of ADG cells, and sex respectively. Table rows were the categories of infection intensity. For differences in gonad condition at each site, samples of the whole culture period were pooled because of the lack of mussels in some category of infection intensity in some monthly samples from Sites 1 & 2. In addition, samples from Site 3 corresponding to 4 different periods of the gonad were treated separately, since infection prevalence was higher at this site.

Goodness of fit of the sex ratio to 1:1 was tested by chi-square tests (Sokal & Rohlf 1981). Association between postspawning stress and progression of infection was assessed in 2 different ways. (1) Mussels sampled from Site 3 in months in which both pre- and postspawning gonad stages occurred were pooled into 2 groups: those showing prespawning stages and those

in postspawning stages. Association between infection intensity and pre- or postspawning gonad stage was assessed by *G*-tests of independence. (2) Spearman rank correlation coefficients ( $r_s$ ) between the percentage of mussels with a heavy infection of every monthly sample and the percentage of mussels in a postspawning stage in the same month were calculated using SOLO statistical software.

Mussels with light and moderate infections were pooled together because of the lack of significant differences between these categories for every considered variable. Samples of the period from the start of cultures to the first detection of cases of infection were not considered for statistical analysis. Mussels infected by trematods were not used in any comparison because of the well-known detrimental effects of these parasites on the gonad of the host (reviewed by Lauckner 1983).

**RESULTS**

**Infection and gonad development**

It was observed at every site that, after pooling monthly samples, the lower the intensity of infection, the higher was the percentage of mussels showing stages of gonad progression (I, II, III A & III C). On the

other hand, the higher the intensity of infection, the higher was the percentage of mussels showing stages of gonad regression (III D) or resting (0) (Fig. 2).

Differences in gonad development between mussels with heavy infection and the remaining mussels were significant at every site. Differences between non-infected mussels and those with light or moderate infection were not significant at any site (Table 1).

**Intensity of infection and gonad condition in 4 different periods at Site 3**

According to the gonad condition observed in every noninfected mussel from Site 3, 4 different periods were distinguished in the mussel gonad cycle at this site (Fig. 3C): (1) the period September–December 1988 was characterized by active gametogenesis; (2) during the period January–March 1989 most mussels remained ripe; (3) the period April–May 1989 was characterized by early spring spawning and subsequent restoration of the gonad to ripeness; and (4) in the period June–September 1989, after a new spawning, reabsorption of the gonad took place, although some mussels were involved in new restoring and spawning sequences. The resting stage was very reduced and a new gametogenic cycle started at the end of this period.

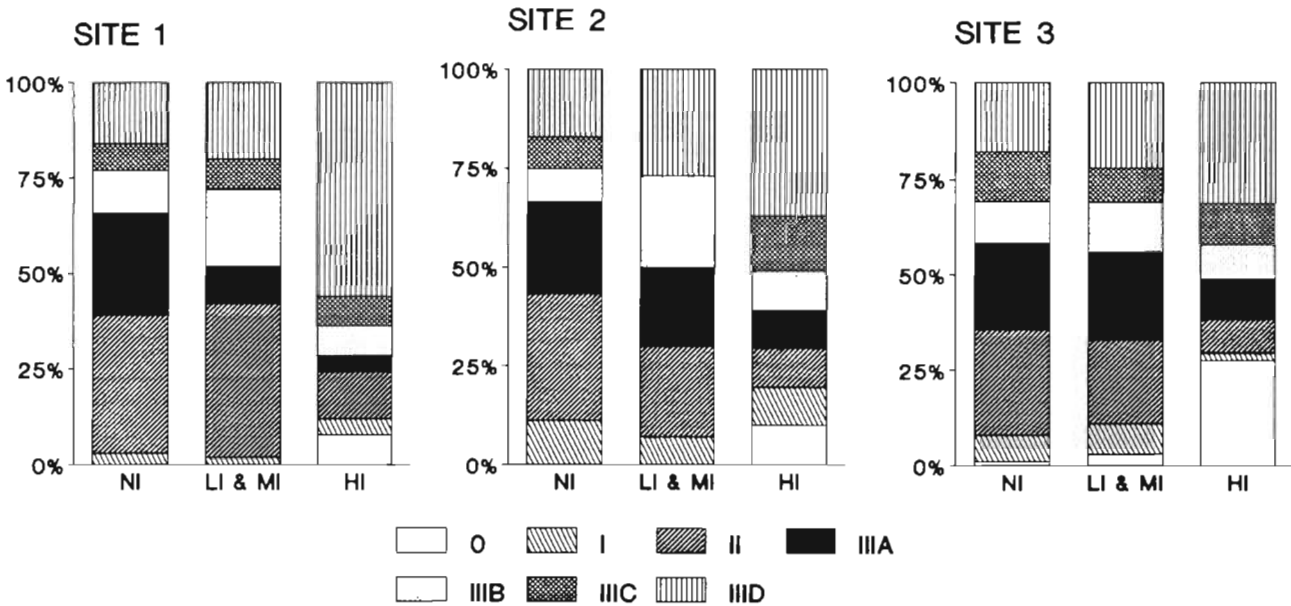

Fig. 2. *Mytilus galloprovincialis* infected by *Marteilia refringens*. Distribution of mussels according to gonad stage and intensity of infection at the 3 sites. Samples of the whole culture period were pooled. Bars correspond to infection intensity classes – NI: noninfected; LI & MI: lightly and moderately infected; HI: heavily infected. Percentages of mussels corresponding to each gonad stage are identified by different bar patterns – 0: resting; I: multiplication of gonia; II: progression of gametogenesis; III A: ripe; III B: spawned; III C: restoration; III D: reabsorption

	HI vs NI, LI and MI	467	6	53.30 ***

There was no significant difference in gonad development among infection intensity classes in the period of active gametogenesis. However, differences between the class of heavy infections and the other 2 classes grouped were significant in the remaining periods (Table 2). In the period characterized by predominance of ripe stage, heavily infected mussels showed higher percentages of spawned and reabsorbing stages. In the period characterized by gonad restoration, around 50 % of heavily infected mussels showed reabsorbing stage. In the period June–September 1989, 50 % of heavily infected mussels showed resting stage and no case of restoration or ripe gonad was found in this infection intensity class (Fig. 4).

### Infection and ADG cells

Abundance of ADG cells was used in this study as an index of the level of stored reserves. The monthly variation of the mean abundance of ADG cells occurring in the mantle of noninfected mussels throughout the culture period at Site 3 involved the following pattern: ADG cells started to appear in the mantle by July 1988.

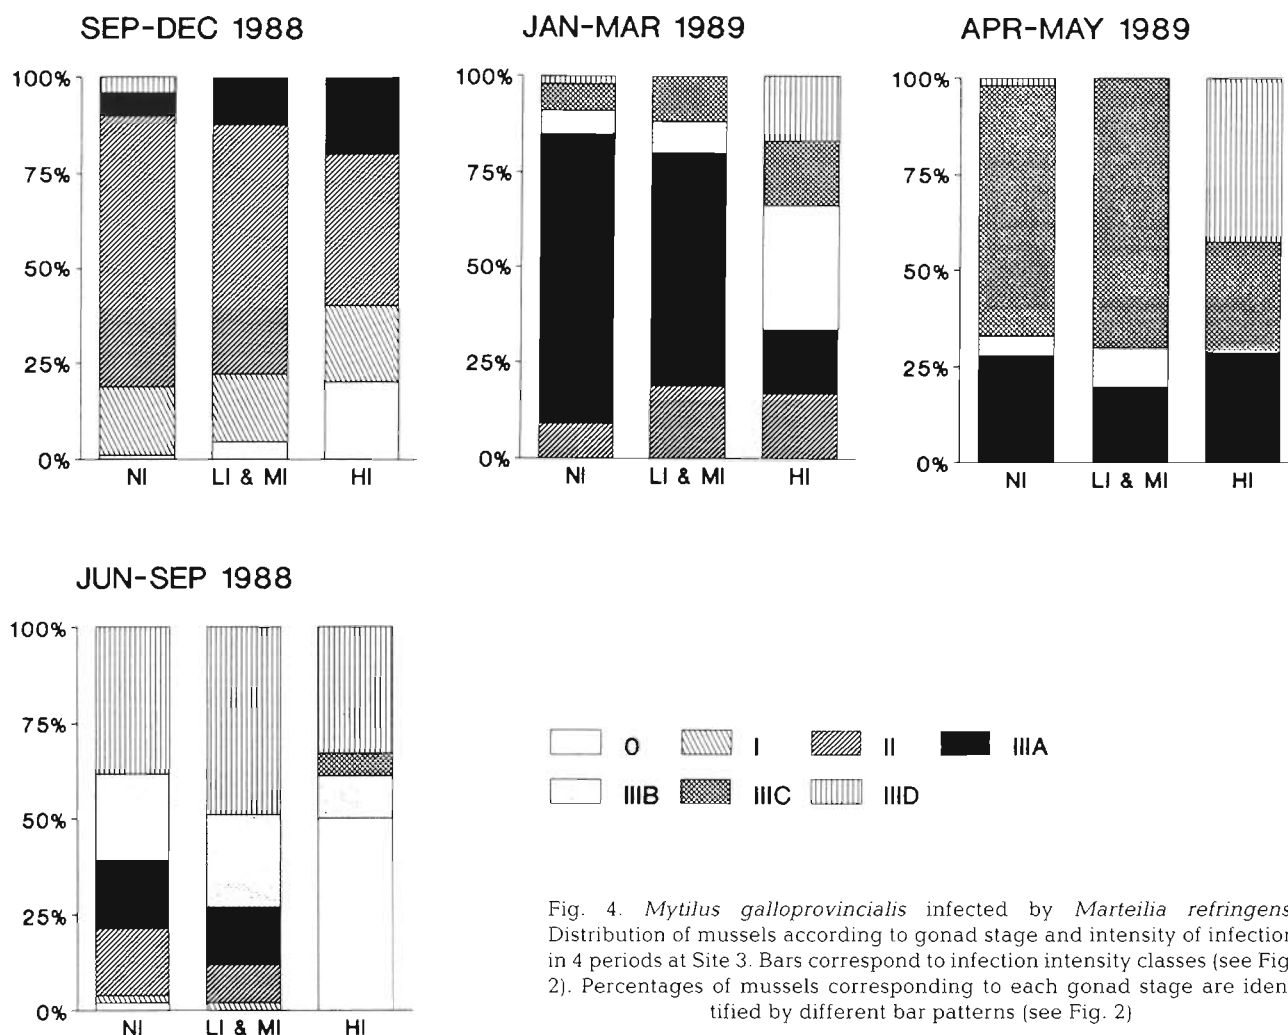

Fig. 4. *Mytilus galloprovincialis* infected by *Marteilia refringens*. Distribution of mussels according to gonad stage and intensity of infection in 4 periods at Site 3. Bars correspond to infection intensity classes (see Fig. 2). Percentages of mussels corresponding to each gonad stage are identified by different bar patterns (see Fig. 2)

Their abundance increased during the summer and the highest values were recorded during autumn, when gametogenesis was in progress. As mussels became ripe, the abundance of ADG cells decreased. A new cycle in the occurrence of ADG cells in the mantle started after the spring spawning (Fig. 3A). Similar patterns of variation were recorded at the other sites.

The percentage of heavily infected mussels without ADG cells was 70 to 80 % at the 3 sites, whereas it did not exceed 50 % in any of the other classes of infection intensity at the 3 sites (Fig. 5). Differences in abundance of ADG cells between pairs of infection intensity classes were significant in most cases (Table 3).

#### Sex and infection

Differences in the sex ratio among different infection intensity classes were not significant at any site. Sex ratios did not significantly deviate from 1:1 in any infection intensity class at the 3 sites (Table 4).

Bars correspond to infection intensity classes (see Fig. 2). Percentage of mussels corresponding to each class of abundance of ADG cells (0 to 5) are identified by different bar patterns

**Postspawning and progression of the infection**

Prespawning stages (II and III A) and postspawning stages (III B, III C and III D) coexisted in the period January-March 1989 at Site 3 (Fig. 3). In this period, heavy infections were significantly more frequent in mussels after spawning as compared with the other classes of infection intensity (Table 5).

Percentage of postspawning stages (III B, III C & III D) and percentage of heavily infected mussels in each sample were significantly correlated at Site 2 ( $r_s = 0.74$ ,  $n = 15$ ,  $p < 0.01$ ) and Site 3 ( $r_s = 0.73$ ,  $n = 16$ ,  $p < 0.01$ ), but not at Site 1 ( $r_s = 0.23$ ,  $n = 12$ ,  $p > 0.05$ ) (Fig. 6).

**DISCUSSION**

Results demonstrate that there is a negative association between infection by *Marteilia refringens* and the development of mussel gonad. The heavier the infection, the less developed was the gonad. Nevertheless, differences in gonad development were significant only between the class of heavily infected mussels and the noninfected class, and between the former and the other 2 classes grouped, at every site.

Two types of storage cells occur in the mantle of mussels: vesicular cells and ADG cells. Regression of the ADG cells occurs during gametogenesis by a lyso-

somal autophagic mechanism (Bayne et al. 1982, Lowe et al. 1982). Gonad cycle and variation of mean abundance of ADG cells observed in noninfected mussels at Site 3 showed that gametogenesis leading to early spring spawning was accomplished by utilizing storage products accumulated during the previous summer and autumn. Subsequent rapid sequences of gonad restoration and spawning in late spring and summer used the energy coming from concurrent feeding directly. Thus, *Mytilus galloprovincialis* exhibits both conservative and opportunistic reproductive strategies at this site (Bayne 1976). A similar combination of both strategies was described by Rodhouse et al. (1984) based on mussels *M. edulis* cultured on suspended ropes.

*Marteilia refringens* infection progresses through the digestive epithelia of mussels (Villalba et al. 1993); therefore, a direct destruction of gonad by the parasite is not observed, but impairment of the processes of food digestion and absorption would be expected. Absorption efficiency is significantly reduced by heavy infections of this parasite (Villalba et al. unpubl.). The inhibitory effect of *M. refringens* on gonad condition varied depending on season. During the periods of active gametogenesis and ripeness, previous to the spring spawning, gonad development was not significantly influenced by infection, probably because mussels had the opportunity to store the required energy for gametogenesis before becoming heavily infected. However, inhibition of gonad development by infection was clear after the spring spawning, when gonad restoration relied on energy from concurrent feeding. Thus, heavily infected mussels did not restore their gonads after the spring spawning and reabsorbed their gonads, whereas most of the remaining mussels recovered and developed ripe gonads. Summer was the period with the highest differences between classes of infection intensity. A proportion of the noninfected mussels showed new sequences of restoration and spawning before reabsorbing their gonads. Most of them started a new gametogenic cycle by the end of this period. On the contrary, most heavily infected

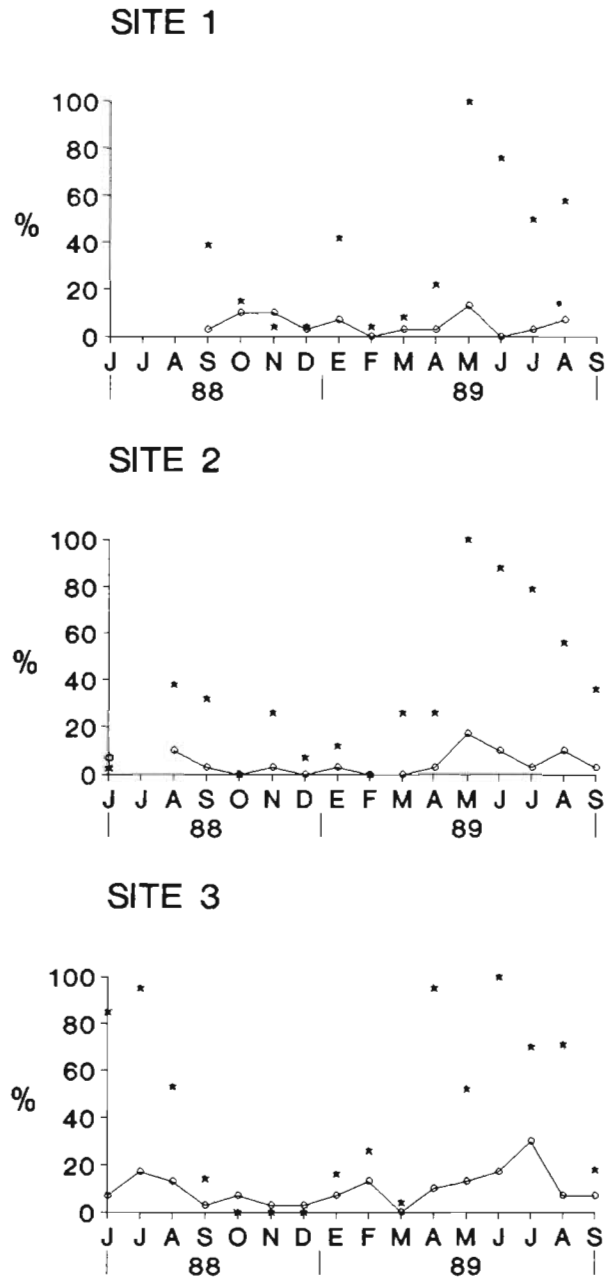

Fig. 6. *Mytilus galloprovincialis* infected by *Marteilia refringens*. Variation of the percentage of heavily infected mussels (solid line) and the percentage of mussels with gonad post-spawning stages (III B + III C + III D) (dotted line) throughout the culture period at the 3 sites. Experimental cultures of Sites 2 & 3 started in February 1988 and first detection of infection occurred in June 1988. Culture at Site 1 started in September 1988. Site 2 was not sampled in July 1988

mussels reabsorbed their gonads to the resting stage and were not able to start a new gametogenic cycle in September 1989. Mussels with light or moderate infections showed an intermediate position. Robert et al. (1991) found some indication of inhibition of gonad de-

velopment in edible oysters *Ostrea edulis* by *M. refringens*. Inhibition of gametogenesis in eastern oysters *Crassostrea virginica* by the haplosporidian parasite *Haplosporidium nelsoni* (Barber et al. 1988a, Ford & Figueras 1988, Ford et al. 1990) and the apicomplexan *Perkinsus marinus* (Mackin 1962) was also detected.

Inhibition of ADG cell development is clearly associated with *Marteilia refringens* infection. The heavier the infection, the lower was the abundance of ADG cells in the mantle. Differences were significant among different infection intensity classes at every site with a sole exception. The highest prevalence of *M. refringens* occurred in July, when active energy storage was in progress in noninfected mussels. Those infected mussels that did not store energy would not be able to develop their gonads properly in autumn (Bayne et al. 1982), and many of them would probably die because of their poor condition. Interference by *M. refringens* in the processes of feeding and absorption of food materials would in part explain the impairment of ADG cell development. In addition, infection is a stressing factor that could induce higher energetic demand on the mussel (host reaction, competition for resources) leading to reallocation of reserves, and thus explaining the loss of ADG cells (Bayne et al. 1982, Love & Pipe 1986).

Effects on bivalve energy budgets by other parasites have also been reported. The parasite *Haplosporidium nelsoni* causes significant reduction of clearance rates and condition index of *Crassostrea virginica* (Newell 1985) and depletion of reserves (Barber et al. 1988b). Respiration rates of the oyster are also affected by this parasite in thermal stress conditions (Littlewood & Ford 1990). Glycogen depletion in oysters *Ostrea edulis* associated with *Marteilia refringens* infections was reported (Robert et al. 1991).

No difference in susceptibility to progression of infection was detected between males and females, with regard to sex ratio and infection intensity. Moreover, a similar mortality rate between sexes can be assumed.

The percentage of heavily infected mussels in each monthly sample was significantly correlated with the percentage of mussels in postspawning stages at 2 of the 3 studied sites. Moreover, heavy infections were significantly more frequent in mussels after spawning in the only period in which prespawning and postspawning stages coexisted at Site 3. These results could suggest that stress after spawning enhances the progression of the infection. On the contrary, Ford & Figueras (1988) did not find evidence of enhancement of *Haplosporidium nelsoni* infection in *Crassostrea virginica* by postspawning stress. Energetic cost of reproduction and subsequent postspawning stress become

higher as the mussel grows (Kautsky 1982, Worrall & Widdows 1984, Emmett et al. 1987). That could contribute to explain the lower prevalences observed during the first year of culture at the 3 sites.

*Acknowledgements.* We are grateful to the mussel farmers Mr Armando Otero, Mr José Padín and Mr Rouco Varela for their cooperation with the experimental cultures. We also thank Dr José Molaes for his suggestions on statistical treatment and Dr José Fuentes for critical review of the manuscript. Ms Maribel Meléndez, Ms Teresa Andrade and Ms Elena Penas provided technical assistance for histological technics. This research was supported by funds of the Ministry of Fisheries and Aquaculture of Galicia (Spain).
