ABSTRACT: We report on the histopathological changes occurring in the thymus of coho salmon *Oncorhynchus kisutch* experimentally infected with *Renibacterium salmoninarum*. Coho salmon were intraperitoneally infected, and the thymi were collected weekly from 1 to 7 wk post-infection, and processed for ultrastructural study. The thymus appeared to be infected only in fish collected at 6 and 7 wk post-infection. The first stage of the infection was characterized by the presence of a low number of bacteria scattered in the connective tissue of the capsule. Further progression of the thymic infection was characterized by the rupture of the capsular-thymic barrier, and by the bacterial colonization of the subcapsular and inner zones of the parenchyma, where the bacteria were located mainly in macrophages, but also apparently in pale reticular-epithelial cells and in thymocytes. Other reticular-epithelial cells, and the vascular trabeculae, remained free of *R. salmoninarum* during the initial stages of the infection. In severely infected thymi, necrosis of the parenchyma of the subcapsular and inner zones, and bacterial invasion of the trabeculae occurred. The integrity of the pharyngeal epithelium covering the thymus was not affected during the infection.

KEY WORDS: BKD · *Renibacterium salmoninarum* · Histopathology · Thymus · *Oncorhynchus kisutch* · Fish

INTRODUCTION

Bacterial kidney disease (BKD) is a chronic systemic disease, caused by the Gram-positive bacterium *Renibacterium salmoninarum* (Sanders & Fryer 1980, Fryer & Sanders 1981, Austin & Austin 1993, Evenden et al. 1993, Fryer & Lannan 1993). BKD is characterized by a granulomatous inflammatory response (Wolke 1975), and shows a marked affinity for kidney tissue (Belding & Merrill 1935, Earp et al. 1953). Histopathological studies have demonstrated that natural and experimental infections with *R. salmoninarum* result in granulomas in the kidney, spleen, liver, and muscle (Wood & Yasutake 1956, Bruno 1986), and glomerulonephritis (Young & Chapman 1978, Sami et al. 1992). Also the brain, gills, and the circulatory system are affected (Wood & Yasutake 1956), and the disease

causes anaemia and destruction of the haematopoietic tissue (Wood & Yasutake 1956).

Renibacterium salmoninarum is considered to be an obligate pathogen (Evenden et al. 1993), and different studies indicate that this is an intracellular pathogen, which is able to survive and multiply intracellularly in host macrophages (Young & Chapman 1978, Bruno, 1986, Bandín et al. 1993). Due to the intracellular location of *R. salmoninarum* it is assumed that a major part of the fish defensive response is played by cell-mediated immune mechanisms (Evenden et al. 1993, Sakai et al. 1993). Several studies have demonstrated that fish suffering natural and experimental infections or vaccinated against BKD are able to mount a specific, but low humoral immune response against *R. salmoninarum* (Paterson et al. 1981, Bruno 1987, Kaattari et al. 1989, Sakai et al. 1993). The lack of protective immunity after vaccination or natural infection (Elliot et al. 1989, Sakai et al. 1993) has been correlated with immunosuppression produced by *R. salmoninarum*

* Addressee for correspondence. E-mail: villena@ibm.net

products, such as the p57 antigen (Evenden et al. 1993). This immunosuppression affects the cellular and humoral immune responses (Turaga et al. 1987, Evenden et al. 1993), as well as other non-specific defence mechanisms, including the activation of macrophages (Sakai et al. 1991)

The thymus of fish is considered to be the equivalent of the mammalian thymus, and is involved in the maturation of T-cells (Ellsaesser et al. 1988, Chilmonczyk 1992). Although fish T-cells are poorly phenotypically and functionally characterized (Chilmonczyk 1992), they probably mediate T-cell functions in fish, such as graft rejection, mixed lymphocyte reaction, helper function, delayed hypersensitivity, and lymphokine production (Clem et al. 1991, Chilmonczyk 1992). Thus, T-cell functions may be of importance in the host response to *Renibacterium salmoninarum*, either directly via T-helper or T-cytotoxic/suppressor cells, or via various cytokines which, in mammals, regulate many different aspects of the immune response to intracellular parasites (Reed & Scott 1993). Similar cellular (Clem et al. 1991) and cytokine-mediated (Secombes 1991) mechanisms are present in fish.

In spite of a number of immunological and histopathological studies on BKD, no attention has been paid to the thymus in natural or experimentally infected fish. In this work we describe the ultrastructural changes occurring in the thymus of coho salmon *Oncorhynchus kisutch* experimentally infected with *Renibacterium salmoninarum*. The study is part of a larger one the structural and functional alterations produced by BKD in the lymphoid organs (Villena et al. 1989, Flaño et al. 1996).

MATERIAL AND METHODS

Salmon. Fingerling (6 to 8 cm in length) coho salmon were kept in 1 m³ circular tanks supplied with 12°C, pathogen-free flow-through well water under natural photoperiod conditions, and fed daily with Oregon Moist Pellets (Bioproducts, Warrington, OR, USA) at the Oregon State University Salmon Disease Laboratory (Corvallis, OR).

Experimental infection. Infected fish were held in 130 l tanks supplied with flow-through water from the same source as described above. Thirty salmon (10 fish per tank) were injected with a single dose of 0.1 ml (OD₅₀₀: 1.0) of a broth culture of *Renibacterium salmoninarum* D6 isolate (C. Banner) in saline. Ten non-infected salmon, maintained in the same conditions as described above, were used as controls. Fish were sampled at 1, 2, 3, 4, 5, 6, and 7 wk post-infection (w.p.i.) for routine histology techniques. For the electron microscopy study, samples were taken at 2, 6, and

7 w.p.i. At each sampling, 3 infected and 1 control salmon were euthanized by anaesthetic overdose using a 200 mg l⁻¹ solution of MS-222 (Sandoz). The fish were then bled by severing the tail and the thymi were aseptically removed.

To confirm the identity of the bacterium in the tissues of the challenged fish, sampled tissues (cryostat sections of kidney, spleen, thymus, and liver) were examined by the indirect immunoperoxidase technique (Graham & Karnovsky 1966), using a monoclonal antibody (3H1) specific for the p57 protein of this pathogen (Wiens & Kaattari 1991).

Electron microscopy. Small pieces of the thymi were fixed for 4 h in 2% glutaraldehyde in cacodylate buffer, 0.1 M, pH 7.2, at 4°C. Tissues were then post-fixed at 4°C for 1 h in 1% osmium tetroxide in the same buffer, dehydrated in acetone, and embedded in Araldite (Durcupan). Semithin (1 µm thick) and ultrathin sections were cut on a Reichert UM-3 ultratome with glass knives. Semithin sections were stained with a 1% aqueous solution of toluidine blue in borax. Ultrathin sections were transferred to copper grids, stained with uranyl acetate and lead citrate (Reynolds 1963) and observed in a Jeol-100C electron microscope at 80 kV.

RESULTS

The progression of the infection was documented by the appearance of external signs of the disease (swollen abdomen, and in some cases moderate exophthalmia) and the presence of internal lesions, which included granulomatous lesions in the kidney, liver, and spleen, and also in some fish the presence of a pseudomembrane covering these organs. The histopathological changes occurring in the kidney and spleen have been described elsewhere (Flaño et al. 1996). *Renibacterium salmoninarum* was considered to be the causative agent of the infection in the challenged fish, as the kidney, spleen, liver, and thymus contained Gram-positive rods, which were stained with the 3H1 monoclonal antibody anti-p57 protein (Villena et al. 1989).

The anatomical location and structure of the thymus in the control coho salmon was similar to that described for this organ in rainbow trout (Chilmonczyk 1983, Castillo et al. 1990). The thymus was delimited by a connective capsule (Fig. 1A), and the parenchyma consisted of 3 different regions (Fig. 1A): (1) a subcapsular area, which contained thymoblasts, limiting reticular-epithelial cells apposed to the basal membrane of the capsule, and large subcapsular reticular-epithelial cells; (2) an inner zone, containing dense populations of small thymocytes arranged in a matrix

of dark reticular-epithelial cells, and ovoid pale reticular-epithelial cells; and (3) an outer zone, externally limited by the pharyngeal epithelium, which contained a low number of thymocytes and densely arranged reticular-epithelial cells. The thymic parenchyma was traversed by vascular trabeculae running from the capsule (Fig. 1A), which were delimited by peritrabecular reticular-epithelial cells, and contained blood vessels surrounded by loose connective tissue.

The thymi appeared infected only in fish collected at 6 and 7 w.p.i., at which stage most of the fish showed severe internal lesions, including haemorrhages and renal liquefaction. No infected fish survived over 7 w.p.i. In the thymus, the first stage of the infection was characterized by the presence of a low number of scattered bacteria located in the connective tissue of the capsule (Fig. 1B), which was highly colonized by lymphoid cells, monocytes, and heterophiles, and showed haemorrhages (Fig. 1B). Further progression of the thymic infection was characterized by an increase in the number of bacteria in the capsule, and presence of bacteria in the subcapsular and inner zones of the parenchyma (Fig. 1C). In the capsule, masses of bacteria occurred in association with the basal membrane, which forms part of the capsular-thymic barrier (Fig. 1C). Most bacteria in the capsule were located extracellularly (Fig. 2A), but fibroblasts also appeared to be invaded by *Renibacterium salmoninarum* (Fig. 2A). The necrosis of the connective tissue was accompanied by the disruption of the collagen fibres and of the basal membrane (Fig. 2A), and necrosis of the limiting reticular-epithelial cells (Fig. 2B).

In the parenchyma, bacteria were located mainly in the cytoplasm of macrophages (Figs. 1C, 2C & 3A), some of which appeared lysed (Figs. 2C & 3A). Often, the macrophages contained large cell debris, possibly of host-cell origin (Fig. 3A). The bacteria also appeared frequently colonizing the cytoplasm of pale reticular-epithelial cells (Fig. 3B), while most peritrabecular, dark reticular-epithelial cells (Fig. 3C) and those of the outer zone (Fig. 2C) were free of *Renibacterium salmoninarum*. Most trabeculae were also free of bacteria (Fig. 3C). Some thymocytes, mainly those located near other heavily infected cell types, contained a large number of bacteria and appeared lysed (Figs. 2C & 3B, C). The integrity of the pharyngeal epithelium covering the thymus was not affected during the infection, and although bacteria were present in the branchial cavity, they did not invade the epithelium (Fig. 2C).

In the more heavily infected thymi, the number of bacteria increased in the subcapsular and inner thymic zones, and disorganization and necrosis of these zones (Fig. 1D), which contained numerous pyknotic cells

and macrophages with large residual bodies, also occurred. At this stage, most cells in the parenchyma appeared to be infected, and bacteria colonized the vascular trabeculae (Fig. 3D).

DISCUSSION

Four to 5 wk after experimental infection with *Renibacterium salmoninarum*, most inner organs were invaded by the pathogen (Flaño et al. 1996). However, infection of the thymus occurred more slowly. Thus, the thymus appeared infected only after the pathogen had spread throughout most of the other tissues. The major route of entry of bacteria into the thymus seemed to occur via the connective tissue of the capsule. Although bacteremia has been reported to be the main route by which tissues become infected (Wood & Yasutake 1956, Young & Chapman 1978, Speare et al. 1993), we did not observe bacteria in the thymic blood vessels until the parenchyma was completely necrotic. This may be due to the specific organization of the thymic vascularization, which comprises a continuous endothelium and basal membrane, and is surrounded by the peritrabecular reticular-epithelial cells that form the so-called blood-thymic barrier (Zapata 1981, Castillo et al. 1991, Chiltonczyk 1992). The presence of a similar anatomical barrier in the brain (the blood-brain barrier) has been implicated also in the relative protection of the brain parenchyma against colonization by *R. salmoninarum* (Speare et al. 1993).

The pharyngeal epithelium covering the thymus, the only barrier separating the external environment from the thymic parenchyma, seemed to be impenetrable to *Renibacterium salmoninarum*. In several samples, bacteria could be observed in the gill chamber, closely apposed to the pharyngeal epithelium, but no bacteria were found invading this epithelium. The origin of such bacteria is uncertain, but it may be from the water contaminated with faeces released by the infected fish (Mitchum & Sherman 1981), or from external haemorrhages of the infected gills.

The relative resistance of the thymus to the infection might be explained by the transcapsular route followed by *Renibacterium salmoninarum*. Invasion of the thymic parenchyma occurred only after the thymic capsule was breached. Disruption of the capsular barrier occurred only in areas where the extracellular bacteria were closely apposed to the barrier's components (i.e. the thymic basal membrane and the limiting reticular-epithelial cells). This suggests that *R. salmoninarum* is able to release 'short-range' extracellular products, capable of digesting both the extracellular matrix of the connective tissue and the thymic

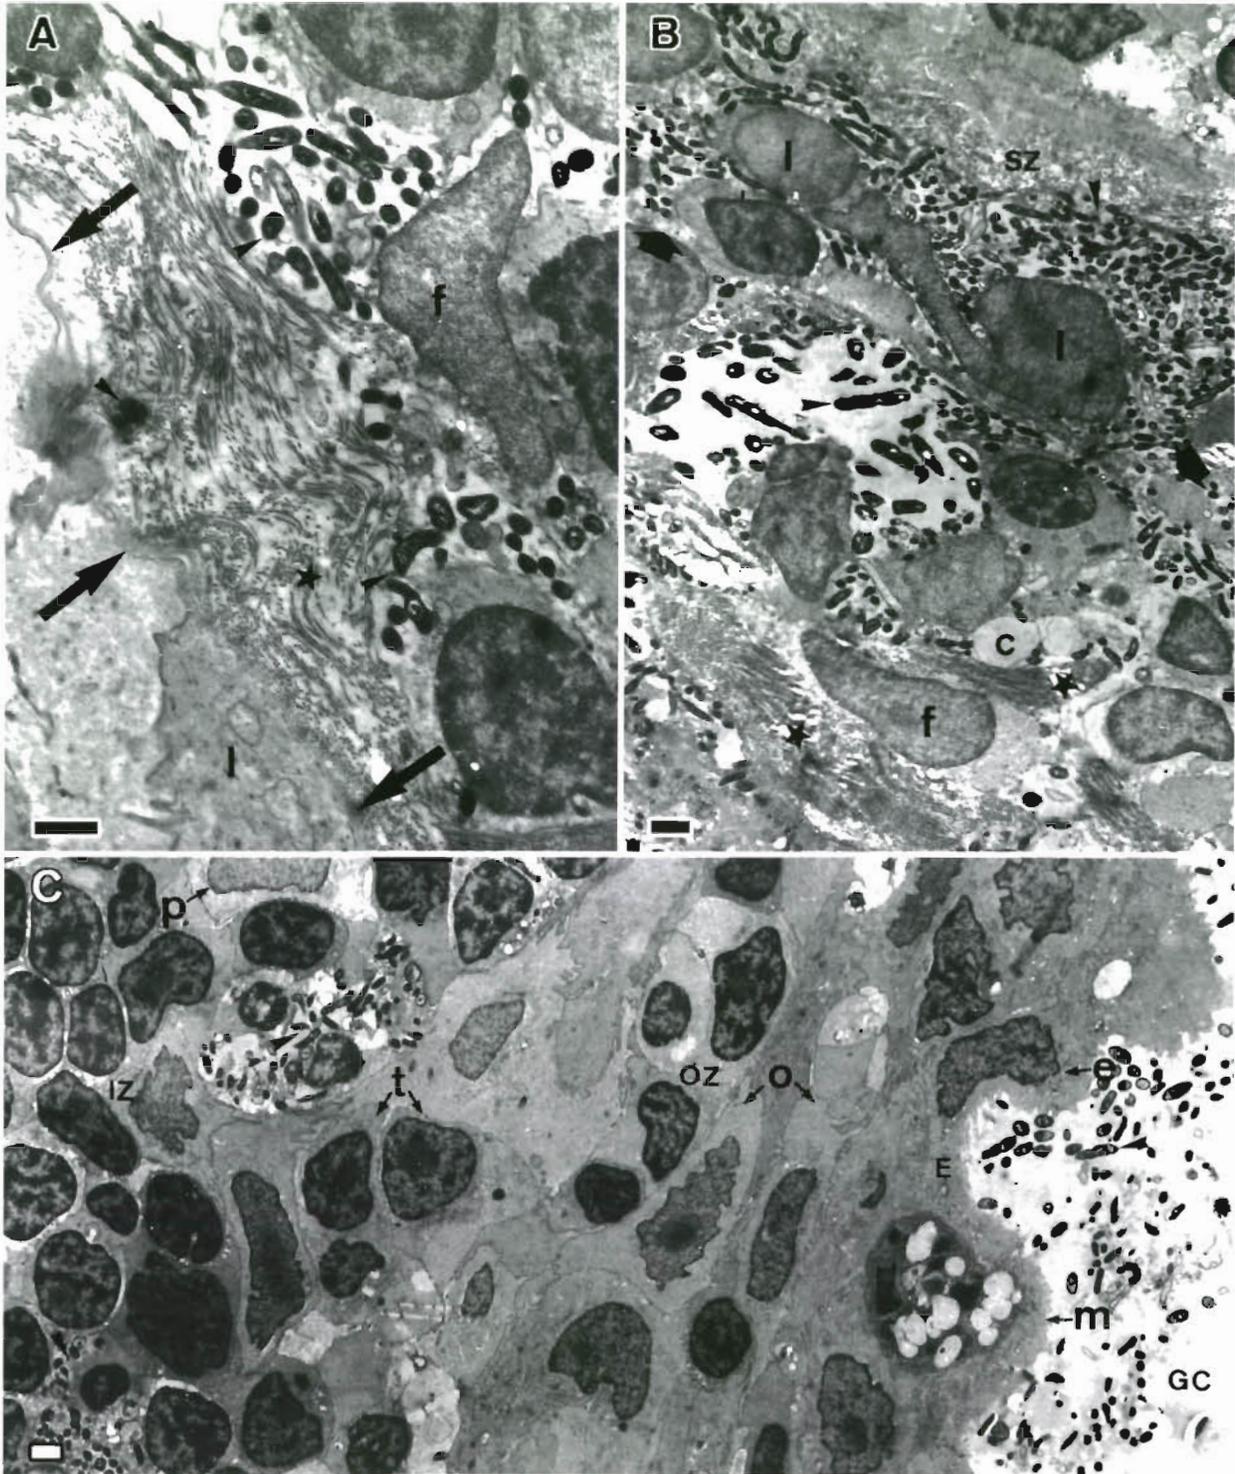

Fig. 2. Ultrastructure of the thymus in *Renibacterium salmoninarum*-infected coho salmon *Oncorhynchus kisutch* at 6 w.p.i. basal membrane. The production of such products by the bacterium is suggested by the strong proteolytic activity found in BKD lesions (Sakai et al. 1989).

The presence of bacteria in the connective tissue of the thymic capsule was accompanied by its infiltration by numerous lymphoid cells (monocyte-macrophages and heterophiles), suggesting the existence of a local inflammatory reaction such as has been described in natural and experimental infections (Villena et al. 1989, Evenden et al. 1993). This response might also have contributed to the infection of the thymic parenchyma via migrating *Renibacterium salmoninarum*-infected macrophages. This source of thymic infection was suggested by the presence of thymic macrophages containing bacteria during the earlier stages of the infection. The macrophages, which initially accumulated in the capsule, may have been infected there by *R. salmoninarum*, and then migrated into the organ carrying the intracellular viable bacterium, as they have been shown to do in other tissues (Young & Chapman 1978, Bruno 1986, Evenden et al. 1993).

After the entry of *Renibacterium salmoninarum* into the thymic parenchyma, it appeared to invade the reticular-epithelial cells and perhaps also the thymocytes. The pale reticular-epithelial cells of the inner zone appeared to be particularly susceptible to the infection, as they were frequently degenerate and invaded by *R. salmoninarum*. In the final stages of the infection, however, all types of reticular-epithelial cells appeared to be degenerate, lysed, or invaded by bacteria. Also, bacteria appeared in the cytoplasm of many thymocytes, most of which appeared to be lysed. Unfortunately, our structural study did not permit firm conclusions on whether the bacteria in the cytoplasm of the reticular-cells and thymocytes represented a specific capacity of *R. salmoninarum* to infect them. Due to the narrowness of the intercellular spaces in the thymic parenchyma, it was not usually possible to observe the cell membranes for their intactness. It is possible, therefore, that the bacterium merely invaded the cytoplasm of previously lysed cells. Cell lysis might have been mediated by the putative membrane damaging factor released by or attached to the bacterial surface (Evenden et al. 1993).

The functional significance of the thymic infection by *Renibacterium salmoninarum* in this study is uncertain because the model studied involved an acute and lethal experimentally induced infection that resulted in the total necrosis of the thymus. More information on the significance of thymic infections might be forthcoming from subacute *R. salmoninarum* infections. Hypothetically, if the pathogen or its products manage to enter the thymus of fish with subacute or chronic infections, this might result in immunosuppression (Turaga et al. 1987, Evenden et al. 1993) and might

contribute to the lack of an effective immunological response to *R. salmoninarum* such as has been noted by various workers (Evelyn et al. 1988, Munro & Bruno 1988). Further studies on the thymic pathology in BKD are needed, especially in natural or in subacute experimental infections, to elucidate this point.

Acknowledgements. We thank Dr Prasad Turaga for conducting the experimental infection. This research was funded in part by the Spanish CYCYT, grant MAR91-0851. Cooperation between the University of León and Oregon State University was funded by grants from the DGICYT (Spanish Ministry of Education and Science) for 'Perfeccionamiento del Profesorado' awarded to Dr Razquin and Dr Villena. E. Flaño was supported by EC contract AIR1 CT92 0036.
