**ABSTRACT:** A culture of *Vibrio harveyi*, isolated from diseased *Penaeus vannamei*, was pathogenic in penaeid shrimp larvae when used in a bath at  $10^5$  cells  $\text{ml}^{-1}$  for 2 h. The resultant disease had characteristics of *Bolitas negricans*, as observed in Ecuadorian hatcheries, namely the development of bioluminescence, reduced feeding and retarded development, sluggish swimming, reduced escape mechanisms, degeneration of hepatopancreatic tissue with resultant formation of necrotic bundles, and increased mortality. Koch's Postulates were confirmed by reisolation and identification of the organism. Histopathology showed the presence of distinctive melanotic tissue aggregates within the hepatopancreas, with immunohistochemistry confirming the presence of large numbers of *V. harveyi* in the intestine and hepatopancreas. These results indicate a suitable infection protocol, which can be used to test the pathogenicity of putative pathogens of penaeid shrimp larvae.

**KEY WORDS:** *Vibrio harveyi* · *Penaeus vannamei* larvae · Pathogenicity

Large-scale losses of larval and juvenile penaeids have been associated with epizootics of *Vibrio* sp. (Lightner et al. 1992, de la Peña et al. 1993, Song et al. 1993, Xu et al. 1993, Hameed & Rao 1994, Lee et al. 1996). In particular, disease outbreaks attributed to luminous *V. harveyi* have been observed in the Philippines (Lavilla-Pitogo et al. 1990), Indonesia (Sunaryanto et al. 1986), Thailand (Jiravanichpaisal et al. 1994), India (Karunasagar et al. 1994), Australia (Pizzutto & Hirst 1995) and Taiwan (Liu et al. 1996). In Ecuador, *V. harveyi* has been implicated with mass mortalities of *Penaeus vannamei* larvae, in the disease condition referred to as *Bolitas negricans*. The condition is characterised by a distinctive pathology of the hepatopancreas, where the tissue degenerates, form-

ing balls which eventually move into the upper gut. At the same time, larvae become bioluminescent, with accompanying behavioural changes and lack of appetite. Fortunately, the disease has been successfully controlled with antibiotics, although antibiotic resistant strains of *V. harveyi* have been recorded (Karunasagar et al. 1994).

It is often difficult to prove pathogenicity of bacterial isolates in penaeids because of the absence of suitable experimental models. Consequently, the aim of this study was to develop a system which would mimic the disease *Bolitas negricans*. Thus, *Vibrio harveyi* was evaluated for pathogenicity in *Penaeus vannamei* larvae.

**Materials and methods. *Penaeus vannamei* larvae:** *P. vannamei* larvae (nauplii VI and protozoa I/II), reared from specific pathogen-free broodstock (Wyban et al. 1993) imported from Hawaii, were obtained from a commercial hatchery (El Rosario S.A., Division Laboratorios) in Ecuador. *P. vannamei* protozoa I, in groups of 400, were maintained in 2 l volumes of aerated hatchery water in 5 l capacity glass bottles. The experimental systems were maintained in a water bath thermostatically controlled at 28°C. The larvae were acclimatised for 24 h prior to use in order to ensure adequate health. Daily feeding was with 100 000 *Chaetoceros* sp. cells  $\text{ml}^{-1}$ .

**Bacterial culture:** *Vibrio harveyi* STD3-101, which was isolated in Ecuador during 1994 from larvae showing clinical symptoms of *Bolitas negricans*, was used in the infectivity experiments. Authenticity of the isolate was verified after Baumann et al. (1984). Long-term storage was at -70°C. Working cultures were maintained on marine 2216E agar (MA; Difco), with subculturing every 1 to 2 wk. In subsequent experiments, the isolate was grown in a shaking water bath for 8 h at 28°C in a 1:10 dilution of lactose broth [1% (w/v) peptone, 0.5% (w/v) yeast extract; pH 7.2] supple-

mented with NaCl to 2.5% (w/v). The bacterial numbers were estimated using an improved Neubauer type haemocytometer at a magnification of  $\times 400$ . Viable counts were recorded from the number of colonies resulting from spreading 0.1 ml volumes onto triplicate plates of MA with incubation at 28°C for 48 h.

**Experimental infection of *Penaeus vannamei* larvae:**

Preliminary experiments showed that *P. vannamei* became infected within 2 h of immersion in bacterial suspensions. Longer periods led to multiplication of the bacteria and extremely high and rapid mortalities. As a result of these preliminary, reproducible experimental infections of *P. vannamei*, larvae were infected by exposure for 2 h to between  $10^4$  and  $10^7$  bacterial cells  $\text{ml}^{-1}$ . Then, the infected water was replaced with fresh ultraviolet-treated seawater. Appropriate controls were established, with water changes only.

The shrimp larvae were examined daily for 10 d for evidence of bioluminescence, changes in behaviour and in feeding patterns, differences in rates of development and mortality. Samples were taken throughout, with 20 individuals removed from each experimental system, then transferred to flamed microscope slides for examination by light microscopy ( $\times 400$ ). In particular, the hepatopancreas was observed for colour and turgidity, and the presence of any abnormalities. The general condition of the penaeids was assessed by observing the filling of the gut, and the presence of faecal strands. The stages of the larvae were recorded after Kitani (1986).

**Microbiological examination:** Groups of 10 larvae from all stocks, the *Chaetoceros* sp. used as food, and water from the experimental system were examined for the presence of *Vibrio harveyi*, prior to use. During the infectivity experiments, groups of 20 larvae were examined microbiologically. For this, the larvae and microalgae were transferred separately to sterile Eppendorf tubes, washed in 0.5 ml volumes of sterile 0.85% (w/v) saline, and homogenised in fresh saline. Dilutions (to  $10^{-6}$ ) of the homogenates and water from the experimental system were prepared in fresh saline, and 0.1 ml volumes were spread over the surface of triplicate thiosulphate citrate bile salts sucrose agar (TCBS, Oxoid) plates with incubation for 24 h at 28°C. Bacterial cultures, which were luminescent and considered to resemble *V. harveyi*, were identified by examination of phenotypic characteristics (Baumann et al. 1984) and by immunoassay.

**Immunoassay by dot and colony blot:** A monoclonal antibody to *Vibrio harveyi* strain STD3-72, which had been obtained from diseased *Penaeus vannamei* larvae during an outbreak of *Bolitas negricans* in Ecuador (French et al. 1986), was used. Dot and colony blots were carried out, using appropriate positive and negative controls, by a modified method of Noel et al.

(1996). The colony blots were prepared by placing 0.45  $\mu\text{m}$  nitrocellulose filters (Millipore) onto TCBS agar plates, which had been inoculated with the culture and incubated for 8 h at 28°C. After 10 min, the filters were removed using flamed forceps, transferred to Petri dishes and left for 30 min to dry. Dot blots were prepared by emulsifying single colonies in 0.5 ml volumes of phosphate buffered saline (PBS; pH 7.2). Volumes (1  $\mu\text{l}$ ) of the bacterial suspensions were spotted onto nitrocellulose filters, which were air-dried for 30 min.

The filters were incubated in PBS + 5% (w/v) skimmed milk (Oxoid) for 45 min to block all the unbound sites. After washing twice, each for 3 min, with PBS + 1% (v/v) Tween 20 (Sigma), the filters were incubated for 45 min with a 1:3000 dilution in PBS + 0.5% (w/v) skimmed milk of the monoclonal antibody. The filters were re-washed, as before, then incubated for 45 min with a 1:15000 dilution of donkey anti-mouse immunoglobulin IgG conjugated with alkaline phosphatase (Sigma) in PBS + 0.5% (w/v) skimmed milk. After further washing, the filters were incubated in the dark for 20 min with bromo-4-chloro-3-indolyl-phosphate/nitroblue tetrazolium (Sigma) in Tris buffer (0.5 mM  $\text{MgCl}_2$ ) at pH 10.0. The reaction was stopped by washing in PBS + 2 mM of EDTA. Positive reactions resulted in the formation of an intense blue colour, whereas negatives remained colourless.

**Histopathology and immunohistochemistry:** Diseased larvae, in groups of 10, were fixed in Davidson's fixative for 6 h (note: greater periods led to deterioration of the larvae), transferred to 70% ethanol until required and then processed in mesh bags (Life Sciences International). The paraffin wax embedded larvae were sectioned, mounted on poly-L-lysine (Sigma) coated slides, and stained with Harris' haematoxylin and eosin (Bucke 1989) or used for immunohistochemistry. For this, an immunoassay was developed using polyclonal antibodies produced in a female New Zealand white rabbit to *Vibrio harveyi* STD3-101 (titre by whole cell agglutination  $\geq 1:8192$ ). The tissue sections were incubated for 30 min at 22°C with 5% (v/v) sheep serum [Scottish Antibody Production Unit (SAPU), Carlisle, Scotland] in PBS. After washing 3 times for 5 min with PBS, the sections were incubated for 1 h with a 1:2000 dilution in PBS + 0.5% (v/v) sheep serum (SAPU) of the polyclonal antibody to *V. harveyi*. The sections were re-washed thrice for 5 min in PBS, before incubation for 1 h with a 1:250 dilution in PBS + 0.5% (v/v) sheep serum of goat anti-rabbit IgG conjugated with alkaline phosphatase (Sigma). After further washing, 1 mg  $\text{ml}^{-1}$  of Fast Red ( $\alpha$ -naphthol; Sigma) was added for 10 min. The reaction was monitored to avoid overdevelopment of the stained tissues, and stopped by incubation with PBS + 2 mM EDTA. The

sections were counterstained with haematoxylin (Bucke 1989), dehydrated, and mounted in a xylene substitute mountant (Life Sciences International). Positivity was indicated by the presence of a pink coloration, which contrasted well with the natural pigmentation of the tissues.

**Results and discussion.** At the onset of the pathogenicity experiment, *Vibrio harveyi* was not detected in larvae, algae or water samples. Furthermore, throughout the duration of the experiment, *V. harveyi* was not detected in any of the uninfected larvae (Table 1). Control individuals developed normally, and by the time of mysis (Day 4), they were extremely active and difficult to catch. Conversely, larvae which were infected with an inoculum of  $10^7$  cells took longer to reach mysis stages (MI/II; Day 8), were sluggish, swam near the bottom of the tank, and were easily caught. Larvae infected with  $10^5$  and  $10^6$  cells  $\text{ml}^{-1}$  displayed similar signs, although less pronounced, whilst those challenged with  $10^4$  cells  $\text{ml}^{-1}$  showed no differences to the controls. *V. harveyi* was detected in all infected larvae, even those which lacked pronounced pathology. Bioluminescence was observed up to Day 6 in larvae infected with  $>10^5$  cells  $\text{ml}^{-1}$  (Table 2). Clinical signs of *Bolitas negricans* were most evident at 2 d post-infection in shrimp larvae infected with  $10^5$  to  $10^7$  cells  $\text{ml}^{-1}$ , although pathology was still observed to the end of the experiment. Larvae infected with  $10^4$  cells  $\text{ml}^{-1}$  also showed pathology, although less chronic and only in the first 2 d after infection. The highest mortalities were recorded during the change from protozoa III to mysis I. By the end of the experiment, survival in larvae infected with  $10^4$ ,  $10^5$ ,  $10^6$  and  $10^7$  cells  $\text{ml}^{-1}$  was 90, 53, 81 and 51%, respectively. Mortalities were not recorded among the controls.

The hepatopancreas of control larvae maintained a good shape and colour and the guts were filled with food. In early, or acutely, infected individuals changes were seen in the internal structure of the hepatopancreas. In particular, the organ was less turgid, and

bundles of tissue were beginning to form. The hepatopancreas of chronically infected larvae were grey and emaciated, with balls of necrotic tissue (from the hepatopancreas) blocking the upper gut. Apparently, the larvae were unable to ingest, and the gut was totally devoid of food. At this stage, the larvae were close to death.

Examination of fixed tissues from healthy larvae showed structural integrity within the hepatopancreas and gut (Fig. 1). In comparison, infected protozoa III, which were exhibiting classical signs of *Bolitas negricans*, had a distinctive pathology, characterised by the formation of bundles of necrotic tissue within the hepatopancreas (Fig. 2). Where necrotic bundles had formed, the emaciated walls of the hepatopancreas were particularly evident.

By immunohistochemistry, *Penaeus vannamei* larvae infected by immersion with  $10^5$  to  $10^7$  cells  $\text{ml}^{-1}$  revealed the presence of *Vibrio harveyi* in large numbers in the upper areas of the gut. Positive staining was also observed within hepatopancreas tubules, indicating a degree of colonisation in that area. There was no evidence for the presence of bacteria associated directly within necrotic bundles in the hepatopancreas. Uninfected tissues, serving as controls, were uniformly negative.

Changes in environmental conditions are capable of retarding and enhancing the virulence of *Vibrio harveyi* (Prayitno et al. 1995). Therefore, when attempting to assess the potential to elicit disease, it is necessary to be careful about the storage and culture of the isolate, because of the subsequent effect this may have on pathogenicity. From the experiments undertaken here, Koch's Postulates were fulfilled, insofar as after causing disease signs in larvae, the bacteria were reisolated in pure culture and identified as *V. harveyi*. Furthermore, disease symptoms associated with *Bolitas negricans* were seen only in larvae infected with *V. harveyi*, whereas controls remained healthy throughout the experiments. A distinctive histopathology was observed, and correlated with the presence of *V. harveyi* in infected larvae, as elucidated by immunohistochemistry. Indeed, following the course of infection, a range of severities, with highest doses of

Fig. 1. *Penaeus vannamei*. Healthy hepatopancreas and gut in control larvae. Scale bar = 0.5 mm

bacteria producing the most clear pathology, was observed. The low level of mortality recorded in infected individuals was probably attributable to the previous good health status of the larvae, as evident from a lack of mortality in controls.

It was clear that, at the end of the study, although no sudden mortality was observed, survivors were still exhibiting pathology and behavioural changes, indicative of damage to the digestive system. Coincidentally, a similar situation sometimes occurs in Ecuadorian hatcheries, where *Bolita negricans* affected larvae

appear to recover, but then slowly die off before reaching later post-larval stages.

In conclusion, a reproducible infection model has been described, which is suitable for assessing pathogenicity in penaeid shrimp larvae. In this study, disease resembling the condition *Bolita negricans* was elicited, solely arising from an artificial infection of *Vibrio harveyi*.
