ABSTRACT: Extinction risk is closely tied to body size, home range, and species distribution. Quantifying home range is critical for conservation, and can enable the use of concepts such as ‘umbrella species’, whose conservation protects other species due to shared habitat. To determine the value of the humphead wrasse as an umbrella species for coral reef conservation, we conducted a multi-year study of humphead wrasse home range at Palmyra Atoll, Central Tropical Pacific, tagging juvenile, female, and male individuals with acoustic transmitters. We quantified home range using 2 metrics, length and area, and determined if these metrics were related to the sex and maturity status of the individual. We recorded individual movements during 5030 fish-days, yielding detailed records for 14 individuals comprising 3 juveniles, 5 females, and 6 males. The home range of humphead wrasse measured over a 2 yr study was 0.4 to 14 km and changed with ontogeny. Females had larger home ranges than other reef fishes studied to date ($n = 68$), indicating value as an umbrella species for coral reefs. We compared the home range of the species to the size distribution of tropical marine protected areas (MPAs), and used a model to estimate the MPA length necessary to retain humphead wrasse. Most MPAs are too small to effectively protect the humphead wrasse.

INTRODUCTION

Species loss is accelerating globally, causing concerns that we are entering the 6th mass extinction (Barnosky et al. 2011). Positive feedbacks may result in accelerating losses, since biodiversity is tied to biogeochemical properties of ecosystems and their resilience (Naeem et al. 2012). Extinction risk in vertebrates correlates with fundamental biological scales: body size, home range, and geographical distribution. Large body size is associated with enhanced extinction risk (Olden et al. 2007), as large species have lower fecundity, slower growth (Cardillo et al.

2005) and are more vulnerable to exploitation (Weaver et al. 1996). A larger home range is more easily fragmented and more difficult to protect (Purvis et al. 2000), and is a predictor of extinction risk (Davidson et al. 2009). A small geographical distribution enhances vulnerability to habitat loss or extreme mortality events (Davidson et al. 2009). These trends are known to occur for marine fishes (Olden et al. 2007).

In oceans, the size of a species’ home range (generally considered to be the range during post-recruitment life stages, i.e. following larval dispersal) is a key predictor of the level of protection offered by marine protected areas (MPAs) (Heupel et al. 2006, Di

*Corresponding author: kevinweng@vims.edu

Franco et al. 2012). Some species range over scales of meters (Lindholm et al. 2006), whereas others range across oceans (Weng et al. 2005). Small-scale MPAs have limited effects for many fish species (Friedlander et al. 2007), particularly those that are more mobile and leave small reserves frequently (Palumbi 2004). Regions with large human populations have very low populations of large-bodied fishes, including top-level predators, whereas areas that are effectively protected from fishing via MPAs or have a low human population density can contain a large number of top-predators (Friedlander & DeMartini 2002, Sandin et al. 2008, Richards et al. 2012). Based on our findings and many others, a major ramping up of conservation efforts is needed (Bellwood et al. 2004).

International trade in wildlife threatens biodiversity and ecosystem function on a global scale and has caused numerous extinctions (Rosen & Smith 2010). Illegal, unreported, and unregulated fishing (IUU) (Borit & Olsen 2012) intersects with the wildlife trade in coral reef systems, where animals are captured alive for sale as food or aquarium animals (Poh & Fanning 2012). Overfishing of many species is occurring, spawning aggregations are targeted (Sadovy de Mitcheson et al. 2008), and destructive fishing practices are causing severe collateral damage to reefs (Johannes & Riepen 1995). Trade bans have failed to control overfishing on coral reefs (IUCN 2010), which face additional challenges, such as acidification, warming, pollution, and habitat degradation (Bellwood et al. 2004). The rapid economic growth of China indicates that demand for luxury seafood products will increase substantially (Fabinyi 2012).

Facing urgent conservation needs, we cannot wait for perfect ecosystem information before taking action (Johannes 1998). Conservation planning has a longer history in terrestrial settings than for oceans (King & Beazley 2005), and the marine realm could benefit from approaches developed on land. Simply protecting areas with high diversity fails to account for the persistence of these protected systems (Nicholson et al. 2006). 'Focal species' provide greater understanding of complex systems (Lambeck 1997) and include the indicator, keystone, flagship, umbrella (Zacharias & Roff 2001), and landscape species (Coppolillo et al. 2004) concepts. The keystone species concept aims to identify a species with the strongest role in ecosystem function, making it very difficult to identify qualifying species (Power et al. 1996). The landscape species concept aims to integrate ecological and human factors, requiring an even greater level of knowledge to apply (Sanderson et al. 2002, Coppolillo et al. 2004). Umbrella species

are those with large home ranges that encompass many sympatric species with smaller ranges (Noss et al. 1996, Berger 1997). Information needs are relatively simple; we need only habitat and home-range data to identify umbrella species, a benefit in marine systems where knowledge of ecosystem function is less developed than on land. Across many taxa, the presence of umbrella species correlates with higher diversity and abundance (Branton & Richardson 2011), demonstrating that it is a powerful conservation tool, albeit a blunt one. All focal species approaches have weaknesses and biases (Coppolillo et al. 2004, Saetersdal & Gjerde 2011), but conservation with available knowledge is preferable to inaction (Wiens et al. 2008).

In marine systems, an umbrella species would have (1) a large home range, (2) the greatest number of sympatric species (i.e. shared habitat requirements), and (3) high vulnerability to fishing or other impacts (Berger 1997, King & Beazley 2005, Butler et al. 2012). While an in-depth analysis of Point 2 is beyond the scope of this paper, the humphead wrasse *Cheilinus undulatus* shares habitat with a diverse community whose benthic habitat is itself alive—the coral reef. The species has a broad Indo-Pacific distribution (Sadovy et al. 2003a), thus occupying the region with the greatest coral reef biodiversity on the planet (Roberts et al. 2002). The humphead wrasse also fulfills Point 3, being one of the largest and most conspicuous coral reef fishes, and one severely overfished through most of its range. Targeting by the live reef fish trade has led to a severe decline in population despite its broad geographic distribution (Poh & Fanning 2012). It is on the IUCN's 'Endangered' list, in Appendix II of the Convention on International Trade in Endangered Species (CITES), and is under consideration for listing according to the US Endangered Species Act. The humphead wrasse is the highest priced species in the live reef fish trade (Sadovy et al. 2003b), and targeting continues despite its rarity (Poh & Fanning 2012). In the absence of home-range data it was not possible to evaluate Point 1. Only 1 publication exists on home range and movement (Chateau & Wantiez 2007), limited to a single individual that departed the small study region after 25 d, compromising the estimate of home range. Therefore, knowledge of the humphead wrasse's home range would allow its evaluation for all 3 umbrella species criteria.

Here we present home-range estimates for the humphead wrasse measured with an acoustic observation network. We compare these estimates to the sizes of existing MPAs in the geographic distribution

of the species' using a retention model, and make recommendations on a MPA scale. We present both home-range area and home-range length (HRL: the longest dimension of a shape; Kramer & Chapman 1999), and discuss the value of the humphead wrasse as an umbrella species for conservation of coral reef fishes.

MATERIALS AND METHODS

Study species

The humphead wrasse *Cheilinus undulatus* has a broad Indo-Pacific distribution (Sadovy et al. 2003a). It is a protogynous hermaphrodite that matures as a female at about 5 yr of age and 35 to 50 cm total length (TL), with some individuals changing to mature males at about 9 yr of age and 70 to 80 cm TL, and others remaining female (Sadovy et al. 2003a, Choat et al. 2006, Sadovy de Mitcheson et al. 2010). The species reaches 2 m TL and 190 kg, and ages of at least 30 yr (Sadovy et al. 2003a, Choat et al. 2006). The humphead wrasse eats a wide variety of invertebrate and teleost fish prey, and is notable in being one of the few predators of *Acanthaster planci*, the crown-of-thorns starfish (Randall et al. 1978, Sadovy et al. 2003a). Despite the large observation effort by scientists, divers, and fishers, understanding of its spawning behavior was only recently developed (Colin 2010). Only one publication exists on home range and movement (Chateau & Wantiez 2007), limited to a single individual that departed the small study region after 25 d, compromising the estimate of home range.

Field site

We conducted a multi-year study at Palmyra Atoll, Line Islands, Central Tropical Pacific (5.9° N, 162.1° W). Palmyra is one of the few remaining parts of the world with healthy populations of humphead wrasse (Zgliczynski et al. 2013). Palmyra Atoll provided an ideal field site to test hypotheses about home-range size in large coral reef fishes due to the combination of a large-scale reef and the bordering oceanic waters that prevent emigration to other reefs. Palmyra Atoll has approximately 60 km² of reefs and lagoons, and far exceeds the scale of the median reserve today (0.4 km²), as well as the previously published humphead wrasse home range length, which we estimated to be 756 m by measuring the width of the detection ranges in Fig. 1 of Chateau & Wantiez (2007).

Experiment

We deployed a network of 51 acoustic receivers (VR2W, Vemco). Animals with acoustic transmitters (V9, V13, and V16 coded tags, 2 min delay, 193 to 3033 d battery life) were detected when inside the detection radius of a receiver yielding presence-absence data. Fish were tagged in 2010 and 2011, and receivers were downloaded in 2011 and 2012. The network covered all habitats of the atoll (i.e. lagoons, forereef, and backreef areas).

Fish were captured with hooks or by divers using nets, and were placed in a holding tank aboard a boat. Anesthesia was conducted using MS-222; a small incision was made in the abdomen, a transmitter was inserted, and the wound was closed using surgical suture. Transmitters and instruments were soaked in povidone-iodine solution. Following surgery fish were placed in the holding tank to recover before being released.

Sex of study individuals

We were not able to determine sex based on morphology because there is no clear sexual dimorphism in the species (Liu & Sadovy de Mitcheson 2011), and we did not want to risk injuring animals by attempting to take gonadal samples. Therefore, we used the data in Table II of Sadovy de Mitcheson et al. (2010) to calculate mean TL for juvenile, female, or male individuals (means were: juvenile, 33.8 cm; mature female, 77.9 cm; and mature male, 104.6 cm). Then, using a *k*-means clustering algorithm with mean TL as input, we classified each of our animals into these 3 classes. We then compared the HRL with class using an ANOVA to check if differences in HRL could be detected between classes. The possibility of primary males <85 cm TL exists (Colin 2010, Sadovy de Mitcheson et al. 2010), so we cannot rule out the possibility that individuals categorized as female were small primary males. In addition, the existence of rare large females (Sadovy de Mitcheson et al. 2010) means there is a possibility that individuals we classified as male were actually female.

Data analysis

We quantified home range using 2 metrics, length and area, and determined if these metrics were related to the total length of the individual. Many animals have asymmetric ranges, so the scale neces-

sary for protection is given by the largest distance to span the home range—the HRL (the distance between boundaries in the longest dimension; Kramer & Chapman 1999). We also calculated home-range area, since many MPAs are categorized by area rather than length. Data were not normally distributed, so we used median and interquartile ranges to report results.

We used 2 different approaches to determine HRL and area: the kernel utilization distribution (KUD) and the minimum convex polygon (MCP). Since the KUD method is less sensitive to outliers, we report KUD values in the results, and both in Table 1. These methods were applied to locations from each animal calculated at evenly distributed time points using a weighted mean method (Simpfendorfer et al. 2002). Because of the large number of detections (see Table 1), and because of the relative insensitivity of HRL and area to the choice of bandwidth, we used the ‘ad hoc’ method for selecting the KUD bandwidth, which is appropriate for large sample sizes

(Worton 1989). For calculation of both MCP and KUD we used the package *adehabitat* for R Version 3 (R Core Team 2013).

HRL was calculated as the longest dimension of the 95 % KUD, or the longest dimension of the MCP. We then compared HRL with TL using a quadratic regression (with regression parameters β_0 , β_1 , and β_2) to check for significant ontogenetic or sex-based effects. To check the hypothesis that HRL depends quadratically on TL we fitted the model such that:

$$\text{HRL} \sim \beta_0 + \beta_1 \times \text{TL} + \beta_2 \times \text{TL}^2 \quad (1)$$

To determine if our study duration was sufficient to allow for meaningful inference regarding home range, we checked that HRL reached an asymptotic value indicating that extending the study duration would not yield different results. Starting with 1 d of data we calculated 95 % HRL, and repeated for increasingly larger data subsets to produce a cumulative home-range length over time (Heupel et al. 2004).

Table 1. Home range metrics for humphead wrasse *Cheilinus undulatus*. Home range length (HRL) is based on 95 % kernel utilization distribution (KUD) or on minimum convex polygon (MCP). ID: identification number; F: female; M: male; J: juvenile; Q1: 1st quartile; Q3: 3rd quartile

MPA size

We used a global protected area dataset (IUCN & UNEP 2009) to determine the area and boundaries of tropical MPAs. To limit the analysis to MPAs containing coral reefs, we excluded all protected areas that did not overlap with the coral reef polygons contained in a coral reef dataset (Burke & Spalding 2011). Using the geographic distribution reported in Sadovy et al. (2003a), we calculated MPA length for each of the coral reef MPAs within the range of the humphead wrasse. MPA length was defined as the largest linear dimension of the protected area, and was calculated using a rotating calipers method on the minimum convex polygon enclosing the MPA.

To compare MPA length against the home-range scale of humphead wrasse, we estimated juvenile, male, and female retention rates for different sizes of MPAs. Our simulations were conducted for putative MPAs across a large range of sizes, and not for specific MPAs that exist around the world. We assumed a linear coastline with uniform habitat (Moffitt et al. 2009), and simulated the spatial distribution of fish home ranges as a uniform random variable. This means that the individual fish was the same as its home range, for the purposes of the simulation, and that the distribution of fish was random. The number of individuals simulated was a function of the viable population size for a species, so resource managers should choose a number appropriate for their case. We created random simulations of home-range distribution ($n = 10\,000$ home ranges run^{-1}) in MPAs of different length (L , in units of HRL) and defined home range (R) as the sum of all home ranges or parts of home ranges expected to fall within the MPA divided by the sum of all the home ranges. We used a large number of individual fish per run (10 000) to ensure that results were not controlled by stochastic processes.

$$R = \frac{\sum_{i=1}^n \int_{l_i}^{r_i} g(x) dx}{nH} \quad (2)$$

where n is the total number of simulated home ranges (10 000), i is the i^{th} home range, H is the HRL (which can be treated as 1), x is the length coordinate and $g(x)$ is a function defined to equal H^{-1} inside the bounds of the MPA (situated along the line from 0 to L), and equals 0 outside of it:

$$g(x) = \begin{cases} H^{-1}, & 0 \leq x \leq L \\ 0, & x < 0 \\ 0, & x > L \end{cases} \quad (3)$$

while l_i and r_i are the left and right bounds of the i^{th} home range, defined as the home-range center (h_i) minus and plus half the HRL, respectively:

$$\begin{aligned} l_i &= h_i - \frac{H}{2} \\ r_i &= h_i + \frac{H}{2} \end{aligned} \quad (4)$$

While home ranges in reality are not uniformly distributed due to the uneven distribution of suitable habitat, the distribution of habitat should not affect the expected behavior of our simulation (i.e. patchy habitat distributions are equally likely to reduce or increase retention). The results of our analysis differed for 2 conditions: in the first condition, we constrained the home ranges to be distributed so that their centers always overlapped with the MPA:

$$h \sim U(0, L) \quad (5)$$

This was termed the ‘narrow’ condition and implies that only fish whose home-range centers fall within an MPA can be considered for calculations of retention rate. In the second condition (the ‘wide’ condition), we additionally allowed the home ranges to be distributed so that their edges overlapped the MPA:

$$h \sim U\left(-\frac{H}{2}, L + \frac{H}{2}\right) \quad (6)$$

This more conservative definition, which considers more individuals for calculations of retention rate, always resulted in lower estimates for retention. Both calculations yielded an MPA length (in units of HRL) necessary to achieve a given level of post-recruitment retention. Following a published method (Kramer & Chapman 1999), we chose 90 % retention of individuals inside the MPA as the target ($R \geq 0.9$), but decision makers should choose a target level appropriate to their case. HRLs are a strong function of ontogeny. MPAs that seek to boost the spawning biomass of a species must successfully protect all 3 post-recruitment life stages; therefore, the life stage with the largest HRL (female) was considered to set the MPA length threshold for successful protection.

RESULTS

We captured and tagged 19 humphead wrasse ranging in size from 27 to 109 cm TL (80 cm; 62–97 cm TL [median; Q1–Q3]) during expeditions in 2010 and 2011 at Palmyra Atoll (Table 1). During 5030 fish-days, 188 585 detections were recorded,

yielding detailed movement records for 14 individuals comprising 3 juveniles, 5 females, and 6 males (Fig. 1, Table 1). Home-range metrics were calculated from both KUDs and MCPs; the methods yielded similar values for HRL, but MCP provided larger estimates for area. We report results from KUDs, for which bandwidths averaged 0.06 km (median; Q1–3: 0.03 to 0.13 km).

Home-range scale and ontogeny

The overall KUD-HRL was 3.5 km (median; Q1–3: 2.0–8.6 km; Table 1). HRL varied by stage

(Kruskal-Wallis test: $H = 11.31$, $df = 2$, $p = 0.00$), and was 0.7 km (0.6–0.7 km) for juveniles, 10.3 km (9.2–14.4 km) for females, and 2.9 km (2.2–3.6 km) for males (Fig. 2). Since females had the largest range, they would not be protected by management regimes based on male or juvenile home-range scale. Therefore, females were used to quantify the area required to protect a population. Quadratic regression of HRL versus TL provided a significant fit ($R^2 = 0.689$; t -test for β_2 : $t = -4.17$, $p = 0.00$). That is, for individuals below a peak value (77 cm TL) HRL increased as a function of TL, whereas individuals >77 cm showed a decrease in HRL.

Fig. 1. (A) Home ranges of 14 humphead wrasse *Cheilinus undulatus* at Palmyra Atoll (grey outlines show contours from 0 to 20 m). Track durations ranged from 202 to 394 d. Upper left panel shows nodes of the receiver network; other panels show individual fish. Identification numbers correspond to Table 1 (J: juvenile; M: male; F: female). Green lines show estimated locations used to calculate minimum convex polygons and kernel utilization distributions (KUD). Black outline shows 95% KUD, area, and length given in Table 1. (B) KUD for 1 individual (F3) that was 67 cm total length at time of tagging, tracked for 371 d

Fig. 2. Home range versus body size in the humphead wrasse *Cheilinus undulatus*. (A) Home-range length (HRL) based on minimum convex polygons (MCP), versus total length. (B) HRL using the 95% kernel utilization distribution (KUD) method, versus total length. The red line shows a nonlinear fit to the data, while the assignment of life-stage was made using a k-means clustering algorithm (see 'Materials and methods'). Significant differences exist between life stages

Home-range scale of coral reef fishes

The humphead wrasse had a greater HRL than other coral reef teleost fishes from a wide variety of families (Fig. 3), including the heavily targeted groups Serranidae, Carangidae, Scaridae, Mullidae, and Acanthuridae (Kramer & Chapman 1999). In particular, the median home-range scale of female humphead wrasse (9.7 km) to our knowledge exceeds all other measured HRLs of coral reef fishes, including those reported for juvenile reef sharks of considerably larger body size (Fig. 3; Table S1 in the Supplement at [www.int-res.com/articles/suppl/](http://www.int-res.com/articles/suppl/n027p251_supp.pdf)

Fig. 3. Home-range length (HRL) versus body length for coral reef fishes: 68 species of coral reef teleosts (black circles) and 3 sharks (red diamonds) from the literature (see Table S1 in the Supplement), and data from this study (crosses) for humphead wrasse *Cheilinus undulatus* showing juveniles (red), females (green), and males (blue) (± 1 SD). Dashed line shows a power law regression of the form $y = kL^b$. The regression has a slope of 2.20 (95% CI: 1.83–2.57) and explains 66% of the variability in the data. Humphead wrasse HRL exceeds that of other teleost reef fishes and falls above the regression line

[n027p251_supp.pdf](http://www.int-res.com/articles/suppl/n027p251_supp.pdf)). Using a power-law regression between HRL and body length for 68 coral reef fishes, we calculated that the juvenile, female, and male HRLs are 6.7, 16.7, and 2.9 times larger than expected based on body length alone.

Home-range scale and marine protected areas

We used 2 metrics to evaluate the scale of existing MPAs, based on how many individuals are considered in retention-rate calculations, with the narrow condition being less conservative than the 'wide' condition (see 'Materials and methods'). Our calculations of expected retention rate indicate that the minimum MPA length necessary to achieve 90% retention of female humphead wrasse (median HRL: 9.7 km) is 24.3 km, or 2.5 times the HRL under the narrow condition, which considers fewer individuals, and 87.3 km, or 9 times the HRL under the wide (conservative) condition, which considers more individuals (Fig. 4). Of the 2028 coral reef MPAs that have been established inside the known range of *Cheilinus undulatus*, 23.0% of the MPAs meet the size criterion for 90% retention under the narrow condition and 5.3% meet the criterion for the wide condition (Fig. 5).

Temporal and spatial adequacy of study

Home ranges for all animals were limited in size compared to the size of the study area (Fig. 1). Palmyra's coral reef platform is 19.5 km long based

Fig. 4. Marine protected area (MPA) length thresholds for humphead wrasse *Cheilinus undulatus*. (A) MPA length to achieve 90 % retention of post-recruitment individuals in units of female home range length (HRL). Gray indicates MPA lengths with retention >90 %. Length axis in multiples of HRL to show that MPA size scales with the species being considered. Narrow and wide conditions are shown (see 'Materials and methods'). (B) HRL for females versus size of MPAs within the species' range. Black polygon shows the cumulative frequency distribution of MPA size. Gray shading and black dashed lines show the interquartile range and median MPA lengths with 90 % retention of females, respectively. Females are presented as they have the longest HRL and would not be protected by MPAs designed for males or juveniles. The percentage of MPAs meeting the narrow and wide conditions for median female HRL are 23.0 and 5.3 %, respectively

Fig. 5. Length dimensions for marine protected areas (MPAs) in the Indo-Pacific region. Region bounded by dashed line shows the geographic distribution of humphead wrasse *Cheilinus undulatus* after Sadovy et al. (2003). The color of MPAs is scaled to their length. Of the MPAs, 77 to 94 % are too small to achieve 90 % retention of female humphead wrasse

on NOAA high-resolution bathymetry (www.soest.hawaii.edu/pibhmc/pibhmc_pria_pal_bathy.htm). The median HRL was significantly smaller than 19.5 km (left-tailed sign rank test: $W = 0$, $p = 0.00$; we used non-parametric tests because the distribution of HRL is non-normal, Jarque-Bera test: $JB = 3.01$, $p = 0.05$). This indicates that our study site was large enough to obtain unbiased estimates of HRL.

Tracking durations for the 14 individuals ranged from 202 to 394 d and averaged 373 d (median) (Quartile 1 to 3: 362 to 379 d). Calculating HRL for increasingly larger subsets of data indicated that HRL reached an asymptote for most individuals at a median of 142 d (Quartile 1 to 3: 64 to 184 d; Table 1). The median tracking duration was greater than the median time to asymptote (right-tailed sign rank test: $W = 105$, $p = 0.00$), indicating that the temporal extent of the study was sufficient to quantify HRL. To deter-

mine if animals had a fixed home range that shifted spatially through time (thereby causing HRL to increase through time), we also calculated HRL using moving windows of 1, 2, 7, and 14 d. The maximum HRL during the window width was not significantly different from the maximum HRL across the whole record (Kruskal-Wallis test: $H = 0.55$, $df = 4$, $p = 0.969$).

DISCUSSION

Our data reveal that the humphead wrasse has a well-defined home range that exceeds the scale of most existing MPAs globally. In the face of growing international demand for wildlife products, protection of the humphead wrasse will require much stronger conservation actions. Such actions would

also have major benefits in terms of safeguarding habitat for the entire ecosystem in which the humphead wrasse lives. The humphead wrasse fulfills 3 key criteria for an umbrella species (Caro & O'Doherty 1999, Roberge & Angelstam 2004): a larger home range than sympatric species, a habitat shared with the most diverse coral reef communities (Roberts et al. 2002), and high vulnerability to fishing (Sadovy et al. 2003a). Key considerations for the design of marine reserves and networks include habitat representation, risk, critical areas, MPA spacing, duration, and climate-change resilience (Green et al. 2014). Larval dispersal is an important consideration for the spacing distance between MPAs; while the key ecological determinant for the scale of any individual MPA is the home range of one or more target species (Palumbi 2004). In this study, we focus on the latter question, and the implications of new data on the home range of the humphead wrasse.

Home range of humphead wrasse and the scale of existing marine reserves

Most existing MPAs are too small to protect the humphead wrasse (Figs. 4 & 5). Globally, reserves range from 0.004 to 640 000 km², but the average is small in scale, 1 to 10 km² (IUCN & UNEP 2009). Considerations for the design of reserves and reserve networks include size, spacing, and shape, with the aim of maintaining ecosystem function in the face of fishing, pollution, development, natural disasters, and climate change (Botsford et al. 2003, Friedlander et al. 2003, Shanks et al. 2003, Palumbi 2004, Fernandes et al. 2005, McLeod et al. 2009). The size of reserves should be related to the home range of key species, while the spacing of reserves should be related to distances of larval connectivity (Palumbi 2004). Furthermore, different functional groups and size classes have contrasting responses to marine reserves, with more-predatory and large body-sized species increasing the most after protection and some groups decreasing as a result of predation and other factors (Micheli et al. 2004).

The existing literature suggests that coral reef MPAs should be 4 to 20 km in length (Friedlander et al. 2003, Shanks et al. 2003, Palumbi 2004, Fernandes et al. 2005, McLeod et al. 2009). Our results suggest that MPAs should be roughly an order of magnitude larger (20 to 80 km length) to protect the humphead wrasse. Given this, what benefits would accrue to coral reef ecosystems by scaling up MPAs to protect humphead wrasse?

Comparison of our home-range data with the literature shows that the humphead wrasse is an effective umbrella species for coral reef ecosystems. The median HRL of female humphead wrasse (10.3 km) exceeds all other published HRLs of coral reef teleost fishes, including the heavily targeted families (Fig. 3; references in Table S1). Since this species falls above the body size–home range regression for coral reef fishes, it has more value as an umbrella species than indicated by its size. To realize the conservation benefits of using the humphead wrasse as an umbrella species, a major scaling-up of MPAs will be required. Geographically, the greatest threats to coral reefs overlap with the smallest MPAs in the Coral Triangle (Fig. 5), indicating that this region is of particular concern. The 344 000 km² Great Barrier Reef Marine Park (GBRMP), which constitutes one of the largest MPAs in the world, implemented a zoning plan in 2004 which establishes 20 km as the minimum length of the smallest dimension of any no-take reserve, and, as of 2005, nearly half of the 122 offshore reserves in the GBRMP had been expanded to fit this definition (Fernandes et al. 2005). The use of humphead wrasse as an umbrella species would emphasize similar, or more conservative, standards in spatial management systems for coral reefs across the Indo-Pacific.

Extinction risk in marine fishes

How likely is extinction in marine fishes? Due to large ranges and high dispersal and fecundity, marine extinctions were considered unlikely in the past. However, both extinctions and major range contractions have occurred among marine fishes (Carlton et al. 1999, Dulvy et al. 2003, Sadovy & Cheung 2003). For those species that command unusually high prices, management via Adam Smith's 'invisible hand' does not work (Thornton 2009). The perception of rarity can increase the value of such products (Hall et al. 2008), so hunters and fishers continue to target such species when rare (Price & Gittleman 2007). The humphead wrasse and many sympatric species exist across a vast area of the Indo-Pacific Ocean, so fisheries have little chance of causing extinctions. However, massive habitat loss is possible in the near future, resulting from ocean acidification and compounding stressors (Kleypas et al. 1999, Orr et al. 2005, Doney et al. 2009), meaning that species with large present-day geographic distributions may have small or patchy distributions in the future. Given the potential for such changes, maintaining systems in

their most intact form appears to be a sensible strategy for coral reef resilience.

Reviews of marine extinction highlight species distribution scale as a predictor of risk, but do not discuss individual home ranges. Specific traits are correlated with extinctions (Dulvy et al. 2004), including rarity (Musick et al. 2000), large body size, late maturity (Reynolds et al. 2005), specialized habitat (Musick et al. 2000), narrow depth range (Graham et al. 2011), small geographic range, endemism, sex-changing ontogeny, and trophic category (macrocarivores and mobile invertivores) (Bender et al. 2013). Small body size has also been highlighted (Graham et al. 2011), although this study excluded families such as groupers, snappers, and jacks that skew towards large body size. High fecundity alone does not appear to impart resilience to extinction (Reynolds et al. 2005). Naturally rare reef fish species may be targeted more intensely by predators and wiped out of some localities (Almany 2004). Our results suggest that, in the context of a human-dominated ocean, where human predation can be a key factor shaping community structure, a large home range may increase susceptibility to extinction. Island specialists may have evolved traits for more consistent recruitment than congeners living in extended reef systems, potentially reducing vulnerability (Hobbs et al. 2011). Which of these traits occur in the humphead wrasse? Rarity, large body size, sex-changing ontogeny, and trophic category all put the humphead wrasse on the vulnerable end of the spectrum, while its large species distribution and moderate age at maturity may provide resilience. Many species that are resilient to fishing may have numerous natural refugia (Sadovy & Cheung 2003), but the broad accessibility of coral reefs means that legal or cultural refugia are necessary.

Empowering conservation actions

Global challenges are increasing for marine species and ecosystems (Harnik et al. 2012). As innovations occur in marine conservation and planning (Campagna et al. 2007, Stelzenmuller et al. 2013), we require accurate biological information on which to base new conservation strategies. While we aspire to manage optimally, acting before species or ecosystems are lost means we must manage using the levers we can pull, such as the CITES and the US Endangered Species Act (Harris 2012). Levers also exist where international, national, regional, and local entities are creating and modifying laws, rules, and customs for the

management of fisheries and the conservation of ecosystems (Weeks et al. 2014). Whether the actions are being taken by traditional leaders, fishery cooperatives, governments, non-governmental organizations, or international bodies, the biology remains the same, so conservation actions must be informed by the best available information, and 'scientific advances in fish connectivity ... necessitate refining advice for marine reserve design' (Green et al. 2014, p. 143).

Limited understanding of ecosystem function may make it difficult to find keystones, and systems with high functional redundancy may not have keystone species. In contrast to a keystone species concept, the umbrella species concept does not address the ecological role of a species, or the level of functional redundancy in the ecosystem. It simply addresses the number of other species that are sympatric with the candidate species (Noss et al. 1996, Berger 1997). The umbrella species concept provides us a way to understand the broader implications of the protection of an endangered species. If we protect the habitat of an endangered species with few sympatric species, the system as a whole derives little benefit, whereas habitat protection for an umbrella species, which has many sympatric species, generates great benefits to the ecosystem. Hence, where endangered species are also effective umbrella species, they become the surrogate of an entire ecosystem (Caro & O'Doherty 1999).

The umbrella species concept can be used to develop suites of species that are more representative of ecosystems than single species (Coppolillo et al. 2004), and can be validated through investigations of whether umbrella species and co-occurring species respond similarly to stressors, and to what degree species co-occur (Saetersdal & Gjerde 2011). While umbrella species may not exist for all systems, they are effective in some (Butler et al. 2012, Nicholson et al. 2013), and the concept allows us to act sooner than is possible with the keystone species concept, which requires exhaustive knowledge of functional roles. We suggest that the humphead wrasse, with its large home range and threatened status, can act as an umbrella species for enhanced conservation of coral reef fishes and their habitat.
