

Do spatial differences in the abundance of two serranid fishes in estuaries of tropical Australia reflect long-term salinity patterns?

Marcus Sheaves*

Department of Marine Biology, James Cook University of North Queensland, 4811 Townsville, Australia

ABSTRACT: *Epinephelus coioides* and *E. malabaricus* are closely related species of serranid fishes. They are similar in appearance, occupy the same habitats and are represented in estuaries of north-eastern tropical Australia almost entirely by juveniles. Fish traps were used to sample these 2 species from 3 estuaries on the northeast coast of tropical Australia over a 2 yr period. Patterns of distribution, abundance and size structure were compared. Despite the similarities between the 2 species, they showed quite different patterns of distribution and abundance, both within and between estuaries. In seaward parts of the estuaries the numbers of *E. coioides* were similar to or greater than those of *E. malabaricus*. However, in upstream areas *E. malabaricus* became much more abundant than *E. coioides*. The reasons for this change in dominance are unknown. However, upstream areas of the estuaries exhibited extreme levels of salinity (either hypersaline or hyposaline) and catches of the 2 species correlated with the maximum deviation in salinity. This suggests that if salinity, or some correlated variable, does influence the abundance of the 2 species, it is through long-term effects rather than short-term changes. Regardless of the reason, these spatial differences in abundance suggest that *E. malabaricus* is better equipped to deal with the challenges of estuary life than is *E. coioides*.

KEY WORDS: Estuary · Tropical · Fish distribution · Salinity

INTRODUCTION

Serranid fishes of the genus *Epinephelus* occur in estuaries throughout tropical Australia (Collette 1983, Blaber et al. 1985, Blaber et al. 1989, Sheaves 1992, 1993, 1995a). The species reported most commonly from estuaries in tropical Australia are *E. malabaricus*, *E. tauvina*, *E. coioides* and *E. suillus*. However, much confusion has existed in the classification of fishes of this genus (Randall & Ben-Tuvia 1983, Randall 1987, Randall & Heemstra 1991). It appears that most reports of *Epinephelus* from estuaries in this area refer to 2 species, *E. coioides* and *E. malabaricus*. *E. suillus* is a synonym of *E. coioides* (Randall & Heemstra 1991), and both species have often been misidentified as *E. tauvina* (Randall & Heemstra 1991) which is a species typical of clear-water coral reef areas rather than estu-

aries (Randall et al. 1990). *E. coioides* and *E. malabaricus* are common within estuaries of tropical eastern Australia where, despite occurring to sizes of 400 mm fork length or more (Sheaves 1992, 1993, 1995a), the populations of both species consist almost entirely of pre-reproductive females (Sheaves 1995b).

The distribution of *Epinephelus coioides* and *E. malabaricus* within and between estuaries has received little study. However, in Alligator Creek, an estuary on the coast of tropical northeastern Australia, *E. coioides* and *E. malabaricus* were found to possess quite different spatial distributions (Sheaves 1992). *E. coioides* was the dominant serranid in downstream areas, but catches declined in upstream areas of the creek. *E. malabaricus* showed the opposite pattern with numbers increasing from the lower parts of the creek to upstream areas, where this species became the dominant serranid. If the differences in distribution, abundance and dominance of these congeners are general patterns in estuaries in tropical Australia, it suggests

*E-mail: marcus.sheaves@jcu.edu.au

underlying differences in the biology of the 2 species, possibly in the way they respond to physical conditions in estuaries.

To determine whether the interspecific differences noted by Sheaves (1992) existed in other estuaries in northeastern tropical Australia and whether such patterns were maintained over time, I compared the distributions, abundances and size structures of *Epinephelus coioides* and *E. malabaricus* within 3 estuaries on the coast of tropical northeastern Australia (Alligator, Barramundi and Cattle Creeks) over a 2 yr period. Spatial patterns of distributions and abundances of the 2 species were distinctly different, and the relationship between these differences and variations in water temperature and salinity was investigated.

MATERIALS AND METHODS

Study sites. Sampling was conducted at Cattle (18° 15' S, 146° 15' E), Barramundi (19° 25' S, 147° 10' E) and Alligator Creeks (19° 20' S, 146° 55' E), 3 mangrove-lined estuaries on the northeastern coast of tropical Australia (Fig. 1). The 3 creeks have quite different rainfall patterns. Cattle Creek lies at the southern extremity of the 'wet tropics' and its catchment receives a considerably higher annual rainfall than areas around the other 2 creeks, both of which lie in the dry tropics (Oliver 1978). While the average annual run-off in the catchment area of Cattle Creek exceeds 1000 mm (Bonell 1983), for Alligator Creek annual run-off is about 500 mm and for Barramundi Creek is less than 375 mm (Bonell 1983).

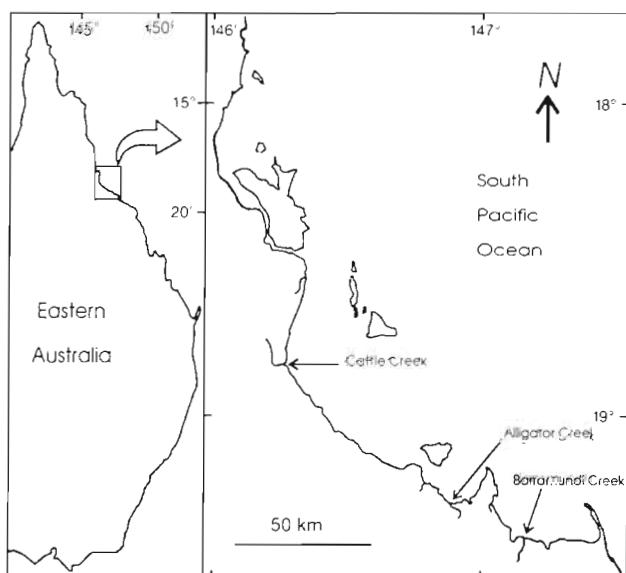

Fig. 1. Locations of Cattle, Barramundi and Alligator Creeks

Sampling. Sampling was conducted using 12 Antilean-Z fish traps (1800 mm long, 1100 mm wide, 600 mm high, plan area approx. 1.53 m², volume approx. 0.92 m³) with 12.5 mm square galvanised steel mesh and straight entrance funnels, and baited with 500 g of Western Australian blue pilchards *Sardinops neopilchardus*. These traps and related sampling protocols are described in Sheaves (1995a).

The navigable portions of Cattle Creek and Barramundi Creek (lower 15 km) were each divided arbitrarily into 4 regions (Bottom, Lower, Upper, Top) representing increasing distance upstream. Each of these regions was approximately 3240 m in length and separated from the adjacent region by a gap of about 500 m. As Alligator Creek had a shorter navigable length only the Bottom and Lower regions were defined. Three traps were used to sample in each region, with no trapping site being used more than once during the study.

Three days of sampling were conducted during the first quarter of the lunar cycle for 24 consecutive cycles, between October 14, 1991 and August 25, 1993. One creek was sampled in each lunar cycle. To enable data to be collected from each creek at a constant interval of 3 lunar cycles, the creeks were always sampled in the same order, first Cattle Creek then Barramundi Creek then Alligator Creek. Thus each creek was sampled on 8 occasions, 3 mo apart. On each occasion, 3 traps were used in each region for 3 d with 2 daytime samples and 1 overnight sample collected from each trap on each day. Although comparing systems sampled in different months has the potential to produce biased results, logistic constraints made this unavoidable. However, the nature and consistency of the patterns found during this study suggests that any such biases are unlikely to be important.

The groups of successive samples from the 3 creeks over a 3 mo period (i.e. Cattle, Barramundi then Alligator) were considered to constitute a season for the purposes of these analyses. However, as there was no gap separating the 'seasons' this division was wholly arbitrary and served only to group the samples broadly into units for temporal comparisons. The seasons were designated as follows: Spring 1991 (October/November/December 1991), Summer 1992 (January/February/March 1992), Autumn 1992 (April/May/June 1992), Winter 1992 (July/August/September 1992), Spring 1992 (October/November/December 1992), Summer 1993 (January/February/early March 1993), Autumn 1993 (late March/April/May 1993), Winter 1993 (June/July/August 1993).

Data analysis. Because only the 2 most seaward regions (Bottom and Lower) could be defined in Alligator Creek the data for *Epinephelus coioides* and *E. malabaricus* were analysed in 2 phases; all regions of

Cattle and Barramundi Creeks (Analysis I), and the lower 2 regions of all 3 creeks (Analysis II).

Previous studies (Sheaves 1992, 1993, 1995a) suggested that *Epinephelus coioides* and *E. malabaricus* would be trapped in low numbers only. Thus it was decided *a priori* to pool data over sites, soaks and days. Data from day and night soaks were pooled also. Thus the data analysed consisted of fish lengths or numbers of fishes in each region of each creek for each season.

Size. Analysis of variance (ANOVA) was used to investigate changes in the mean fork length (FL) of *Epinephelus coioides* and *E. malabaricus*. The factors analysed (Seasons, Creeks, Regions) were considered fixed and orthogonal to each other.

As expected many catch rates were low, with no fish of one or another species being trapped in a number of Season \times Creek \times Region combinations. Due to this paucity of data, particular factor levels were omitted from the analyses of size. For *Epinephelus coioides*, Analysis I included data from the 3 lower regions of Barramundi Creek only, and Analysis II included data from the 2 seaward regions (Bottom and Lower) of Barramundi and Alligator Creeks for all seasons except Winter 1992. For *E. malabaricus*, Analysis I included data for the Bottom, Lower and Upper regions of Barramundi and Cattle Creeks for all seasons, and Analysis II included data for the 2 seaward regions of Barramundi and Alligator Creeks in all seasons except Winter 1993.

Plots of residuals against predicted values and normal probability plots showed no evidence of heterogeneity of variance or non-normality in the data for *Epinephelus coioides* or the data for *E. malabaricus* from Cattle and Barramundi Creeks. However, in the data for *E. malabaricus* from the 2 lower regions of all creeks (Analysis II) there was a tendency for the residuals to increase with the mean, indicating heterogeneity of variance. Therefore a square root transformation was applied to these *E. malabaricus* data resulting in a distribution of residuals that showed no evidence of heterogeneity of variance.

Distribution and abundance. To enable the abundances of *Epinephelus coioides* and *E. malabaricus* to be compared the numbers of the 2 species were analysed together. As a number of Season \times Creek \times Region combinations produced no fish of one or another species, the data were pooled over seasons and only the spatial factors (Creek and Region) analysed. The data in the form of a 3-way contingency table (Species \times Creek \times Region) were analysed using a log-linear model.

Physical variables. On each sampling day the surface and bottom temperatures and salinities of each region were measured as close to low tide as possible. As bottom and surface values were highly correlated only bottom values were analysed. These were thought to better represent the physical conditions the fish would have been exposed to. The absolute value of the maximum deviation in salinity (MSD) away from mean 'normal' seawater salinity (35‰; Kalle 1971) was calculated for each region of each creek and the relationship between catches of *Epinephelus coioides* and *E. malabaricus*, and bottom temperature, bottom salinity and MSD determined.

RESULTS

Size

During the course of the study 280 *Epinephelus coioides* between 120 and 500 mm FL and 334 *E. malabaricus* between 122 and 619 mm FL were trapped in Cattle, Barramundi and Alligator Creeks. The overall size structures of *E. coioides* and *E. malabaricus* (Fig. 2) displayed some differences. The maximum size of *E. coioides* (500 mm) was much smaller than that of *E. malabaricus* (619 mm). Furthermore, for *E. coioides* only 3.2% of fish were greater than 400 mm and only 1 fish was over 460 mm, while for *E. malabaricus* 16.2% of fish were greater than 400 mm. While both species showed a broad mode beginning at around 250 mm, the mode for *E. malabaricus* extended to

about 390 mm, while for *E. coioides* the mode extended to about 330 mm only. The lower ends of the distributions were similar for both species, falling off rapidly from about 250 mm to a minimum of about 120 mm.

There were no clear differences between the fork lengths of *Epinephelus coioides* for any of the variables (Table 1) for Analysis I (3 seaward regions of Barramundi Creek) or Analysis II (the 2 seaward regions of Barramundi and Alligator Creeks), although there was weak evidence of differences between seasons in Analysis II.

For *Epinephelus malabaricus* season had an independent effect on fork length for both Analysis I (3 seaward regions of Cattle and Barramundi Creeks) and Analysis II (2 seaward regions of all 3 creeks) (Table 2). Creek and Region interacted strongly in Analysis I. While there was a very strong Creek effect in Analysis II there was no evidence of differences due to Region (Table 2).

While the mean fork length of *Epinephelus malabaricus* in Cattle and Barramundi Creeks differed with season (Fig. 3), there was no clear pattern; each of the peaks of fork length occurred in different seasons. Size frequency plots of *E. malabaricus* over the 8 seasons also lacked any consistent patterns, as did fork lengths in the 2 lower regions of Cattle, Alligator and Barramundi Creeks.

The mean fork length of *Epinephelus malabaricus* was clearly larger in the Bottom and Lower regions of Barramundi Creek than in the corresponding regions of Cattle Creek (Table 2a; Fig. 4). However, in the Upper region the mean fork length was greater in Cat-

tle Creek than in Barramundi Creek (Tukey's test: $q_{171,6} = 4.247$, $p < 0.05$). Size frequency plots for this interaction (Fig. 5) showed that in the regions with small mean sizes (Bottom and Lower regions of Cattle Creek and Upper region of Barramundi Creek) a small proportion of large *E. malabaricus* were trapped, compared to the Bottom and Lower regions of Barramundi

Creek and the Upper region of Cattle Creek. When the 2 lower regions of Cattle, Alligator and Barramundi Creeks (Table 2b) were compared the mean fork length was larger in Barramundi Creek than in either Cattle Creek or Alligator Creek where the mean sizes were similar (Fig. 6). Size frequency comparisons between creeks (Fig. 7) showed that while Cattle and Barramundi Creeks produced a similar range of sizes

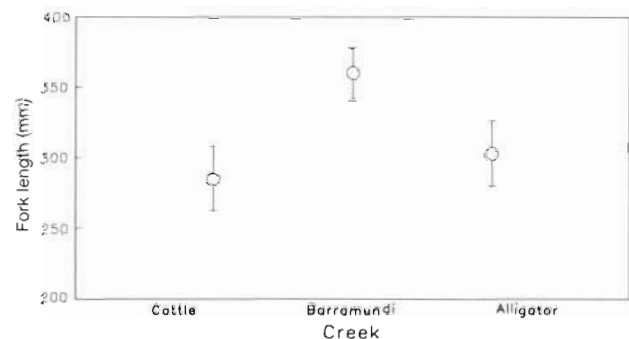

Fig. 6. *Epinephelus malabaricus*. Comparison of the fork lengths of individuals in the 2 seaward regions of Cattle, Barramundi and Alligator Creeks. Data are means \pm 95% confidence intervals

the modal size was larger in Barramundi Creek with a higher proportion of fish in the larger size classes. While the modal fork length was similar in Barramundi and Alligator Creeks, Barramundi Creek had a greater proportion of large fish.

Analysis of the distribution and abundance

For both the comparison of numbers in 4 regions of Cattle and Barramundi Creeks (Analysis I) and the comparison of numbers in 2 regions of Cattle, Barramundi and Alligator Creeks (Analysis II) log-linear modelling yielded the same final model (Table 3). This was composed of 2-way interactions between each of the 3 factors. The numbers of the 2 species differed between both Creeks and Regions independently, and Creeks and Regions interacted in the same way for both species.

For the Species by Creek interaction in Analysis I (Table 3a) the numbers of both *Epinephelus coioides* and *E. malabaricus* were greater in Barramundi Creek than Cattle Creek (Fig. 8a). Furthermore, in Cattle Creek the numbers of *E. malabaricus* were signifi-

cantly greater than the numbers of *E. coioides*, while in Barramundi Creek there was no clear evidence that numbers of the 2 species were different. For Analysis II (Table 3b), while more *E. malabaricus* than *E. coioides* were trapped in Cattle Creek, *E. coioides* was trapped in greater numbers than *E. malabaricus* in Alligator Creek (Fig. 8b). Both were trapped in similar numbers in Barramundi Creek. While numbers of *E. malabaricus* were similar between the 3 creeks, the numbers of *E. coioides* were significantly lower in Cattle Creek than in the other 2 creeks (Fig. 8b).

For the Species by Region interaction, in Analysis I (Table 3a) partitioning of deviance showed that the proportions of the 2 species trapped did not differ significantly between the Lower, Upper and Top regions (deviance = 3.295; 2 df; $p = 0.19253$) with 2 to 3.5 times more *Epinephelus malabaricus* than *E. coioides* trapped in these regions (Fig. 9a). The bulk of the deviance in the interaction was between these 3 regions (Lower, Upper, Top) and the Bottom region (deviance = 17.371; 1 df; $p = 0.00003$) where numbers of the 2 species were similar (Fig. 9a). The numbers of *E. coioides* fell consistently from downstream parts of the creeks to upstream parts; however, after an initial

Table 3. Stepwise fitting (backwards elimination) of log-linear models for the numbers of *Epinephelus coioides* and *E. malabaricus* in 3 estuaries. (a) Four regions in Cattle and Barramundi Creeks (Analysis I), (b) two regions in Cattle, Barramundi and Alligator Creeks (Analysis II). The 3 left-hand columns show the models fitted, and the associated deviance and degrees of freedom. The centre column shows the codes for the current model and the more complex model being compared. The 3 right-hand columns show changes in deviance (Δ Deviance), changes in the degrees of freedom (Δ df) and the probability that the more simple model fits the data adequately. Models containing interactions also contain the main effects composing the interaction. The final model is the model from which no term can be removed without a significant increase in deviance. O: code for the full 3-way model (deviance = 0, df = 0). * denotes the final model

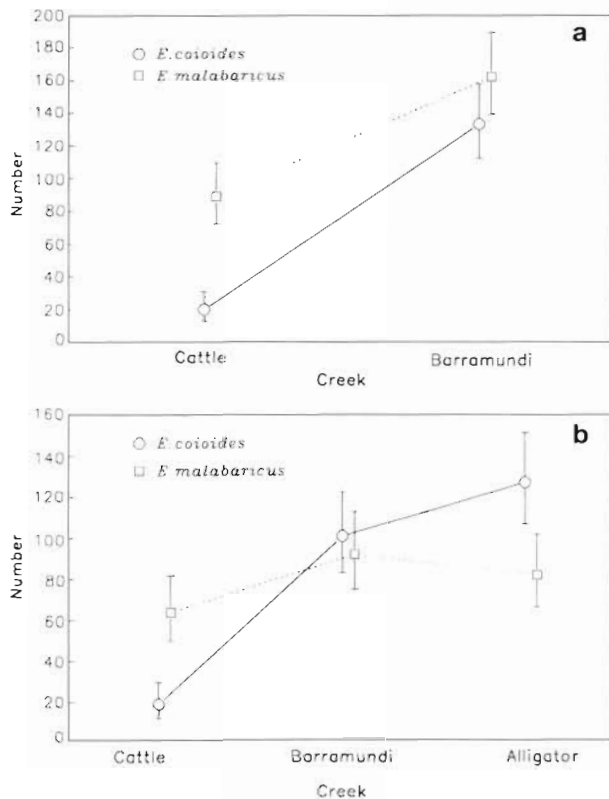

Fig. 8. Effect of the interaction between Species and Creek on the numbers of *Epinephelus coiooides* and *E. malabaricus* in (a) the 4 regions of Cattle and Barramundi Creeks and (b) the 2 seaward regions of Cattle, Barramundi and Alligator Creeks. Data are estimates from the log-linear model \pm 95% confidence intervals

increase in numbers from the Bottom region to the Lower region, the numbers of *E. malabaricus* also declined with distance upstream (Fig. 9a). In Analysis II (Table 3b), the numbers of *E. coiooides* were similar in both regions and in the Bottom region were greater than the numbers of *E. malabaricus* (Fig. 9b). The numbers of *E. malabaricus* increased substantially from the Bottom region to the Lower region, where they were greater than the numbers of *E. coiooides* (Fig. 9b).

For Analysis I (Table 3a) the interaction between Creeks and Regions (independent of species) reflects differences in proportions of *Epinephelus* spp. between regions in the 2 creeks. Notwithstanding this interaction, the numbers of *Epinephelus* spp. in each region of Cattle Creek were consistently lower than in the same region of Barramundi Creek (Fig. 10a). Furthermore, there is an overall similarity in the pattern of change between regions for both creeks. In both cases the numbers of *Epinephelus* spp. tended to be similar in the Bottom and Lower regions before falling away successively in the Upper and Top regions (Fig. 10a). In Analysis II (Table 3b) the numbers of *Epinephelus*

spp. in Cattle Creek were similar in both seaward regions and substantially lower than in either Barramundi or Alligator Creeks (Fig. 10b). The numbers of *Epinephelus* spp. were not clearly different between the Bottom regions of Barramundi and Alligator Creeks, and while there was some evidence that the numbers in the Lower regions were higher for Alligator Creek than Barramundi Creek, the difference was not clear (Fig. 10b). As in Cattle Creek the numbers of *Epinephelus* spp. were very similar in the 2 regions of Barramundi Creek, but in Alligator Creek were greater in the Lower region than in the Bottom region.

Relationship between physical variability and catches

The overall mean, minimum and maximum water temperatures were similar for all 3 creeks, and at any one time the mean temperature differed relatively little between sampling sites within an estuary. Cattle Creek exhibited low salinities (approx. 0 to 39‰; mean

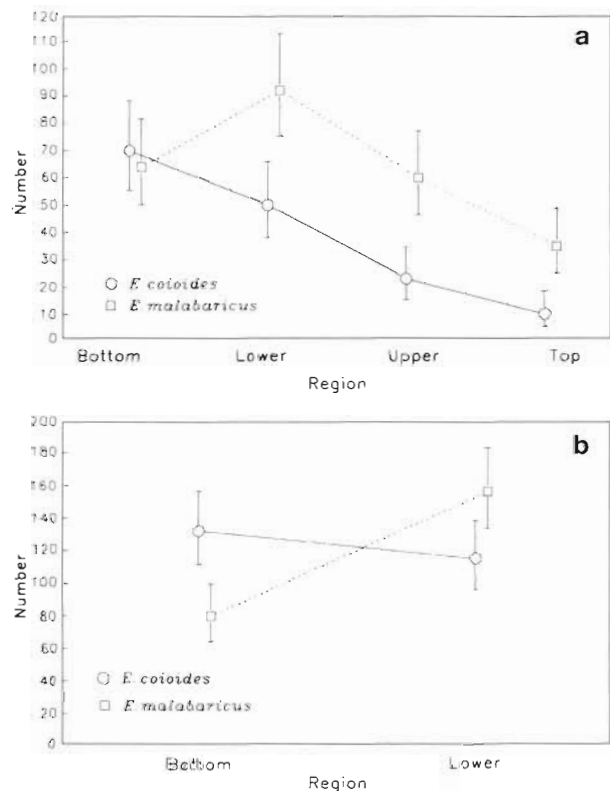

Fig. 9. Effect of the interaction between Species and Region on the numbers of *Epinephelus coiooides* and *E. malabaricus* in (a) the 4 regions of Cattle and Barramundi Creeks and (b) the 2 seaward regions of Cattle, Barramundi and Alligator Creeks. Data are estimates from the log-linear model \pm 95% confidence intervals

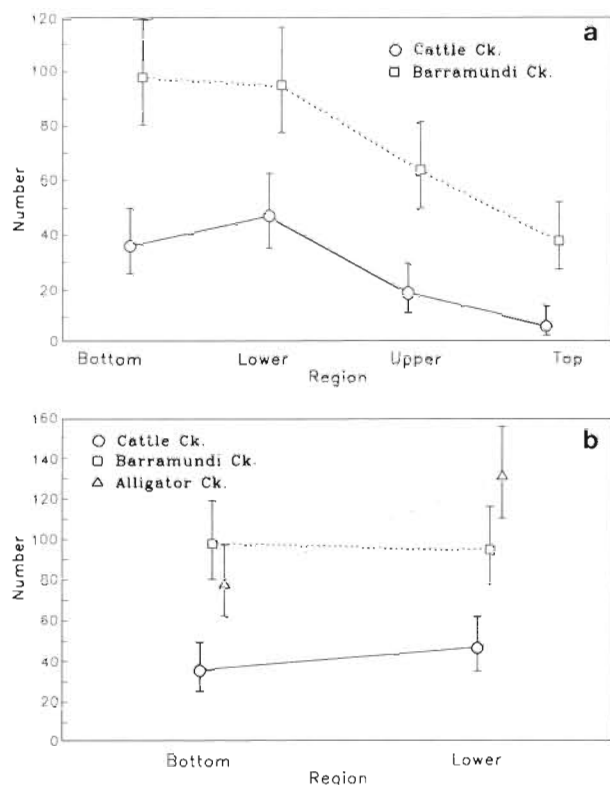

Fig. 10. Effect of the interaction between Creek and Region on the numbers of *Epinephelus* spp. in (a) the 4 regions of Cattle and Barramundi Creeks and (b) the 2 seaward regions of Cattle, Barramundi and Alligator Creeks. Data are estimates from the log-linear model \pm 95% confidence intervals

27.9‰), with both mean and minimum salinities well below 'normal' seawater levels. This was due to continual freshwater inputs from stream flow and flooding in Autumn of each year. Lacking major freshwater inputs during the study period, Barramundi Creek exhibited high salinities (approx. 27 to 55.5‰; mean 41.6‰), with both mean and maximum salinities well above 'normal' seawater levels. Alligator Creek's salinities fell between these extremes.

There was no significant correlation between catch rates of either *Epinephelus coioides* or *E. malabaricus* and water temperature (Table 4). While catches of *E. coioides* per region of each creek per day were significantly correlated with bottom salinity, catches of *E. malabaricus* were not (Table 4). However, the correlations between catches of both species and the maximum deviation in salinity away from normal seawater (MSD) were much stronger (Table 4).

Catches of *Epinephelus coioides* per region declined with MSD both above

(Barramundi Creek) and below (Cattle Creek) normal seawater salinity (Fig. 11a). For both positive (Barramundi Creek) and negative (Cattle Creek) MSDs, catches of *E. malabaricus* first increased then decreased as MSD became greater (Fig. 11b). This pattern was clearer for Cattle Creek than Barramundi Creek where the catch rates for the 3 seaward regions were similar. In Alligator Creek, MSD in the 2 regions deviated from normal seawater in opposite directions so the relation between MSD and catch rates is unclear

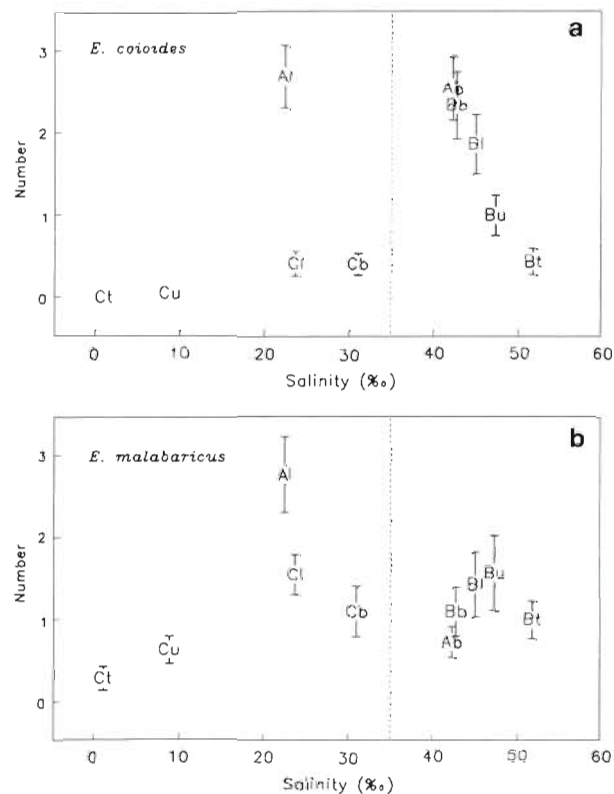

Fig. 11 Relationship between maximum salinity deviation (MSD) and numbers of (a) *Epinephelus coioides* and (b) *E. malabaricus*, trapped per region (b, Bottom; l, Lower; u, Upper; t, Top) in Cattle (C), Barramundi (B) and Alligator (A) Creeks. Data are mean numbers per region per day \pm 95% confidence intervals. Vertical dashed line represents normal salinity (35‰)

Table 4. Correlations between numbers of *Epinephelus coioides* and *E. malabaricus* caught per trap and bottom temperature ($^{\circ}$ C), bottom salinity (‰) and maximum deviation in bottom salinity per region. Data presented are the Pearson product moment correlation coefficient (r) and its associated probability level (p); $n = 240$

	Temperature r (p)	Salinity r (p)	Salinity deviation r (p)
<i>E. coioides</i>	0.0423 (0.5143)	0.1572 (0.0148)	-0.3623 (0.0000)
<i>E. malabaricus</i>	0.1038 (0.1087)	0.0930 (0.1509)	-0.1824 (0.0046)

DISCUSSION

Comparison of the distribution and abundance

The abundances of *Epinephelus* spp. varied between estuary systems. Greater numbers of both *E. coioides* and *E. malabaricus* were trapped in Barramundi Creek than in Cattle Creek (Fig. 8a), and catches of *E. coioides* in the 2 seaward regions of Cattle Creek were substantially lower than in these regions in the other 2 creeks (Fig. 8b). It is possible that the observed low abundances in Cattle Creek may reflect a fundamental difference between this and the other 2 creeks. If so, it would appear that in some way Cattle Creek provides a poorer quality of habitat than Barramundi and Alligator Creeks. One factor that could contribute to the low abundances in Cattle Creek is the occurrence of regular, annual floods. Flooding can influence abundances of estuarine fish populations both directly (Marais 1982, 1983), and indirectly by its influence on salinity (Hoff & Ibara 1977, Marais 1988, Moser & Gerry 1989), which is important in structuring fish communities in tropical estuaries (Quinn 1980). During the present study annual flooding of Cattle Creek caused a marked depression of salinity compared to the other 2 creeks. This annual influx of fresh water and the associated salinity reduction could work in a variety of ways to reduce numbers of the 2 species. Hyposaline conditions would cause osmoregulatory problems (Lasserre 1975, Martin 1988) perhaps increasing mortality rates (Lockwood 1976) or causing fish to move to other areas (Hoese 1960). Low salinity and increased stream flow during flooding may prevent many recruits from entering the creek or at least penetrating upstream areas, or cause newly settled fish to be flushed from the creek. Increased outflow from the creek and associated reduction in salinity may reduce the abundance of prey organisms (Cyrus 1988), thereby reducing the amount of food available to *Epinephelus* spp. If the extra freshwater input to Cattle Creek did affect the abundance of *Epinephelus* spp., the fact that *E. malabaricus* was trapped in greater abundance than *E. coioides* in Cattle Creek but not in the other creeks suggests that *E. malabaricus* may possess greater tolerances to reduced salinity levels.

Despite the plausibility of explanations involving differences in salinity or flooding regimes there are other possible reasons for the changes in abundance of *Epinephelus* spp. between estuaries. It may be that the differences in abundance were specific to the time window in which the study was conducted and not a reflection of long-term patterns. For instance, unusually poor recruitment in Cattle Creek over a number of years while the other creeks received normal or better

than normal recruitment could have produced the observed differences.

In both Cattle and Barramundi Creeks, there was a strong trend for the numbers of both species of *Epinephelus* to decline in an upstream direction (Fig. 10a). Notwithstanding this, the pattern was different for the 2 species. In the seaward regions of Cattle and Barramundi Creeks the numbers of *E. coioides* and *E. malabaricus* were very similar. However, while the numbers of *E. coioides* fell consistently with distance upstream, the numbers of *E. malabaricus* first increased substantially in the Lower region, and while they did fall consistently in the 2 upstream regions they remained significantly higher than the numbers of *E. coioides* (Fig. 9a). When data for Alligator Creek were included and only the 2 seaward regions considered, a change in the dominance of the 2 species was seen, with *E. coioides* more abundant in the most seaward (Bottom) regions and *E. malabaricus* more abundant in the Lower region (Fig. 9b). Although using somewhat different spatial divisions, previous studies of Alligator Creek (Sheaves 1992) also found that *E. coioides* was more abundant in downstream parts and *E. malabaricus* more abundant in upstream parts.

While there were clear differences between the spatial abundances of the 2 species, the reasons for these differences are unclear. It may be that *Epinephelus malabaricus* recruits are better able to access upstream areas than recruits of *E. coioides*, leading to higher recruitment. Alternatively, habitat types, food availability or physical conditions may be less favourable in upstream areas. For instance, while the seaward regions of both Cattle and Barramundi Creeks (where similar abundances of the 2 species occurred) exhibited salinity levels close to that of 'normal' seawater, salinity levels deviated markedly from 'normal' seawater salinity in the upstream regions of both Cattle and Barramundi Creeks. In these areas *E. malabaricus* became the dominant species. This occurred in both creeks despite the deviation from 'normal' salinity being in opposite directions (hyposaline in Cattle Creek, hypersaline in Barramundi Creek). It may be that *E. malabaricus* is more tolerant to variations in salinity away from 'normal' seawater levels than is *E. coioides*. Differences in physical tolerances can be important in causing closely related species of estuary fish to exhibit different patterns of distribution and abundance (Martin 1988), and it is not uncommon for both hypersaline and hyposaline conditions to lead to reduced abundances (Gunter 1961). Indeed the catch rates of both species of *Epinephelus* were correlated with the maximum deviation in salinity (MSD) rather than salinity per se. This suggests that if salinity, or some correlated variable, does influence the abundance of the 2 species it is through long-term effects

rather than short-term changes. Clearly, if a long-lived fish cannot cope with particular salinity levels, a short period of adverse conditions may kill the fish or cause it to migrate away, thereby influencing patterns of abundance for a considerable time into the future. However, the link between catch rates and MSD does not establish causality, only correlation. Many other variables (e.g. water depth and distance from the ocean) also correlate with MSD. Even if the long-term pattern of salinity deviation is a major factor controlling the abundance of *Epinephelus* spp. the relationship is unlikely to be as simple as a direct correlation with MSD. Factors such as the duration and regularity of salinity variation (Lockwood 1976) would probably be as important as the actual deviation from 'normal' salinity.

Comparison of size structures

Over the 3 creeks sampled, the size structures of the 2 *Epinephelus* species demonstrated some marked differences. Both the modal and maximum lengths of *E. malabaricus* were larger than those of *E. coioides*. For both species there was a sharp decline in numbers caught at the lower ends of the size distributions, with few fish below 120 mm trapped. This was well above the minimum size that could have been retained by the 12.5 mm mesh, as the maximum body depth of a 120 mm *E. coioides* is about 28 mm (pers. obs.). Thus the traps should have been able to catch much smaller *Epinephelus* spp. than they did. It appears therefore, that either the smaller fish occupied habitats that were not sampled, or if present in the sampling area, that they exhibited behaviours that meant that they did not enter the traps. If small, juvenile *Epinephelus* spp. do use different habitats to the larger fish it is not clear what these may be. A number of studies have reported *Epinephelus* spp. from coastal seagrass habitats (Blaber et al. 1989, 1992). However, in each case insufficient data are available to determine if small juveniles were common. Conversely, no species of *Epinephelus* were recorded from beam trawl samples (2mm mesh net) from seagrass beds adjacent to Trinity Inlet in northeastern Australia (Coles et al. 1993). Thus it is unclear if small juvenile *E. coioides* or *E. malabaricus* utilise seagrass habitats to a substantial extent. While there are other habitats that could be used by small, juvenile *E. coioides* and *E. malabaricus*, no study of these habitats has reported significant numbers of small juveniles of either species.

No clear spatial or temporal differences were found in the length of *Epinephelus coioides*. This may well have been due to a lack of data preventing viable analysis of *E. coioides* length for many spatio-temporal combinations.

The mean length of *Epinephelus malabaricus* was greater in the 2 seaward regions of Barramundi Creek than in the 2 seaward regions of either Cattle or Alligator Creeks. The reasons for this difference are not clear. These differences in size structure may be a reflection of different settlement histories. For instance, settlement may have been more successful in Barramundi Creek than in the other 2 creeks in the years when the large individuals now present were recruited. However, the mean length of *E. malabaricus* for the Upper region of Cattle Creek was greater than for the Upper region of Barramundi Creek (Fig. 4), making arguments of differential settlement success between creeks difficult to sustain. Apparently more complex explanations, including mechanisms producing within-creek differences, are needed to account for the patterns of spatial differences in length of *E. malabaricus*.

Epinephelus coioides and *E. malabaricus* are closely related species. Both are similar in appearance, occupy the same habitats and are represented in estuaries almost entirely by juveniles (Sheaves 1995b). Despite these similarities, the 2 species showed very different patterns of distribution and abundance, both within and between estuaries. In seaward parts of the estuaries the numbers of *E. coioides* were similar to or greater than those of *E. malabaricus*. However, in upstream areas *E. malabaricus* became much more abundant than *E. coioides*. This change in dominance may relate to differences in the abilities of settling juveniles to access upstream areas. Conversely, it may be that the 2 species differ in their ability to deal with the extreme physical conditions that occur in upstream parts of these estuaries. Regardless of the reason, these spatial differences in abundance suggest that *E. malabaricus* is better equipped to deal with the challenges of estuary life than *E. coioides*.

Acknowledgements. I thank all those who assisted in this project. My particular thanks goes to the Maynard family who provided access to Cattle Creek. I also extend special thanks to B. Molony, G. Russ and D. Williams for their invaluable advice and support during this project.
