

Effects of sediment type and food abundance on the vertical distribution of the starfish *Asterina pectinifera*

Takeo Kurihara*

Ishigaki Tropical Station, Seikai National Fisheries Research Institute, Ishigaki Island, Okinawa 907-0451, Japan

ABSTRACT: The present study investigated how the vertical distribution of the subtidal starfish *Asterina pectinifera* (Müller & Troschel) is affected by sediment type and food abundance. During seasonal surveys over 1 yr in Maizuru Bay, Japan Sea, *A. pectinifera* were abundant in shallow zones (3 to 5 m depth) which were dominated by coarse-grained sediments such as pebbles and oyster shells, while *A. pectinifera* were scarce in deep zones (7 to 11 m depth) which were dominated by fine-grained muddy sediments. Correspondingly, attractiveness of the coarse sediments to *A. pectinifera* was suggested by the following 3 results. First, for each depth, *A. pectinifera* occurred more frequently on the coarse sediments than on the fine sediments. Second, marked *A. pectinifera* translocated into the deep zones returned to the shallow zones, while those released into the shallow zones remained. Third, *A. pectinifera* translocated with the coarse sediments into the deep zones remained, while those translocated without the coarse sediments rapidly dispersed. Such attractiveness of the coarse sediments appeared to arise from not microhabitat but food in these sediments, because *A. pectinifera*, translocated with manipulative coarse sediments into the deep zones, did not differ in number between the sediments with or without microhabitats, but preferred sediments with food retained to those with food removed. In conclusion, the vertical distribution of *A. pectinifera* is affected by that of the coarse sediments, because the coarse sediments provide abundant food.

INTRODUCTION

Factors limiting vertical distributions of organisms have been well studied on intertidal rocky shores by field experiments (Underwood & Denley 1984). These studies deal with various taxa such as algae (Lubchenco 1980), barnacles (Connell 1961a,b, Denley & Underwood 1979, Raimondi 1991), limpets (Creese 1980, Branch 1981), gastropods (Underwood & Barrett 1990), mussels (Paine 1974, Iwasaki 1995a), polychaetes and bryozoans (Keough & Downes 1982). The main factors specified are depth-dependent changes in the abundance and mortality of juveniles (Denley & Underwood 1979, Keough & Downes 1982, Raimondi 1991), competition with other species (Lubchenco 1980), predation (Connell 1961a), desiccation (Iwasaki 1995a) and wave action (Connell 1961b).

Compared with the intertidal zone, few experimental studies on the vertical distributions of organisms have been conducted in the subtidal zone. One feature of the subtidal zone, especially nearshore, is that sediment often shows remarkable vertical changes in terms of grain size or composition. This may influence the vertical distributions of organisms, as sediment frequently affects the distribution patterns of organisms (Snelgrove & Butman 1994).

The first aim of the present study was to investigate experimentally whether the vertical change in sediment type decreases the density of the subtidal starfish *Asterina pectinifera* (Müller & Troschel) with depth. The density of *A. pectinifera* seems to decrease from near the low water level to greater depths, where the sediment type changes from shells and boulders to sand and mud (Kurihara & Yano in press). This change in sediment type causes the vertical change in *A. pectinifera* density; Levin et al. (1987) suggested from their field observations that sediment type may

*E-mail: takeo@snf-its.affrc.go.jp

strongly influence the density of *A. pectinifera*. However, this effect of sediment type has not been experimentally demonstrated.

The second aim of the present study was to investigate experimentally how food and microhabitat on sediment alter the density of *Asterina pectinifera*. The food of *A. pectinifera*, consisting of algae, sea grass, small sessile macrobenthos and detritus (Bak 1981), seems to be more abundant on coarser sediments (Kurihara unpubl.). This seems also true for microhabitats such as crevices and interstices, where *A. pectinifera* hide presumably to avoid predators, competitors, or high temperature associated with sunlight, as has been suggested for other *Asterina* species (Crump & Emson 1983)

MATERIALS AND METHODS

Study site. Field observations and experiments were conducted using SCUBA at 1 to 11 m depths near the Kyoto University Fisheries Research Station (35° 29.2' N, 135° 22.3' E), Maizuru Bay, Japan Sea (Fig. 1). Near the east side of this research station, in a preliminary survey, *Asterina pectinifera* occurred at a high density in association with abundant pebbles and shells. In this area, stations were set at 1, 3, 5, 7 and 9 m depths on 5 transects (A to E; each 50 to 100 m long) and additionally at 11 m depth on 3 transects (A to C).

Surface water temperature ranges from 8.0°C in winter to 27.8°C in summer (Ueno & Satoh 1994), differing between 1 and 11 m depth by <2.3°C throughout the year (Tamura 1992). Because Maizuru Bay is a semi-enclosed embayment, wave-action is weak, except when westerly winds occur in winter or passing boats create wakes. Tides are semidiurnal with a range of 17 cm from mean low water (MLW) to mean high water (MHW) (Maizuru Marine Observatory 1993, 1994).

To examine potential predator and competitor pressure on *Asterina pectinifera*, gastropods and starfishes as found in other studies (Mauzey et al. 1968, Branch & Branch 1980, Stevenson 1992, Okutani 1994) were sur-

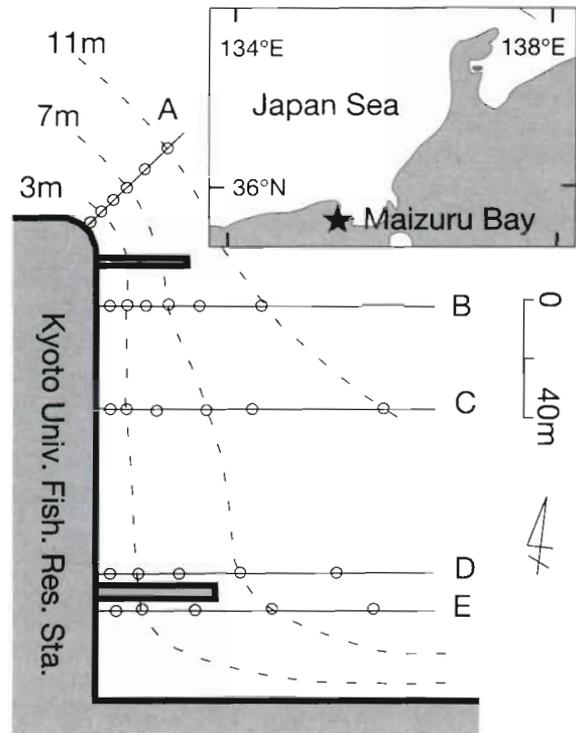

Fig. 1. Maps of the study site. (○) Stations on Transects A to E perpendicular to the shoreline. There is a pontoon between Transects A and B, and between D and E

veyed. A possible predator (starfish *Luidia quinaria*) and possible competitors for food (starfish: *Asterina batheri* and *Astropecten polyacanthus*; gastropods: *Lunella coronata coreensis* and *Omphalius* sp.) were seasonally observed from summer 1995 to spring 1996 at the above-mentioned stations using 4 to 12 quadrats of 0.25 m² to estimate their densities. Mean density for each season and transect (Table 1) was highest at 1 m depth for *Omphalius* sp. and *L. coreensis*, at 3 or 5 m depth for *A. batheri* and *A. polyacanthus*, and was extremely low at each depth for *L. quinaria*.

Observations on sediment. Sediment type at each station was visually divided into fine-grained sedi-

Table 1. Annual mean density (\pm SE, m⁻²) of a possible predator (*Luidia quinaria*) and competitors (*Omphalius* sp., *Lunella coronata coreensis*, *Asterina batheri*, and *Astropecten polyacanthus*) on *Asterina pectinifera*, presented with the number of individuals (N)

ments ('fine sediments') and coarse-grained sediments ('coarse sediments'). More than 60% of the fine sediments consisted of fine mud (<63 μm diameter) at <11 m depths (Saitoh pers. comm.). Coarse sediments consisted of pebbles and bivalve shells. In May 1993, coarse sediments were randomly collected with shovels at 1 to 5 m depths between Transects B and D to measure the longest axis, and were also observed 3 times for 12 quadrats of 0.25 m² at each station to estimate the percentage cover to an accuracy of $\pm 10\%$ (Fig. 2).

Observations on the distribution of *Asterina pectinifera*. Density of *A. pectinifera* was estimated at all stations to examine whether the vertical distribution of *A. pectinifera* corresponded to that of coarse sediments. The number of *A. pectinifera* was counted in a 0.25 m² quadrat thrown 12 times around each station. This survey was conducted twice in summer (June to August 1993), and 3 times in each of winter (December 1993 to February 1994), spring (March to May 1994), and autumn (September to November 1994). Only *A. pectinifera* for which the whole body was visible vertically from above were counted to prevent overestimating the density on complex sediments with abundant microhabitats.

During these surveys, the density of *Asterina pectinifera* for each sediment type was also estimated at each depth. Separately for coarse sediments and fine sediments, the number of *A. pectinifera* was counted at each station at 3, 5, and 7 m depths, where both coarse sediments and fine sediments occurred on each transect (Fig. 2). The number of *A. pectinifera* was summed for each station, and divided by the area of each sediment type at the station. *A. pectinifera* located on the boundary between the 2 sediments or on other sediments (e.g. garbage) were not counted.

Mark-recapture experiments. Marked *Asterina pectinifera* were released and tracked on coarse sediments at 3 to 5 m depths and on fine sediments at >5 m depths; if *A. pectinifera* prefer coarse sediments, then the starfish released on coarse sediments would move at random, while those released on fine sediments would move toward coarse sediments. For the experiments, 238 individuals of *A. pectinifera* were randomly collected from 1 to 9 m depths around the study sites, and individually marked by branding some arms with a soldering iron (see Kurihara 1998). In August 1994 at Transect C (Fig. 1), half of the starfish (i.e. 119 individuals) were released on coarse sediments at 5 m depth and the other half on fine sediments at 7 m depth. Then, 13 and 44 d later, these marked *A. pectinifera* were counted in 63 discontinuous 4 m² plots that were arranged in 7 \times 9 grids in an area of 30 \times 40 m² (see Fig. 4). Each of these 4 m² plots consisted of 16 contiguous 0.25 m² quadrats in which the percentage

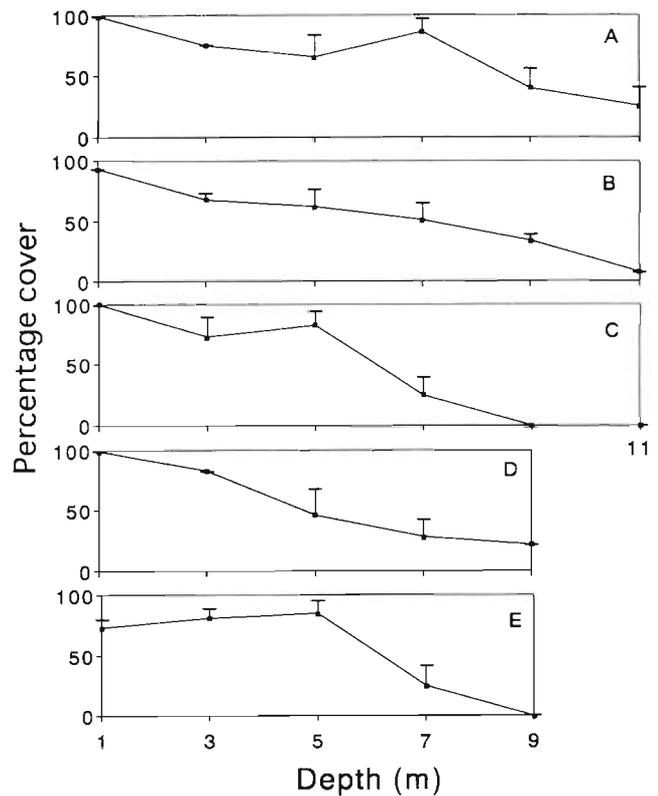

Fig. 2. Mean + SE percentage cover of coarse sediments on Transects A to E during 3 observations in May 1993

cover of coarse sediments was determined in the above-mentioned way. For each *A. pectinifera* found, the identification code and the sediment on which it was located were recorded.

Observations on food and microhabitat. *Asterina pectinifera* is reported to be an omnivorous feeder (Bak 1981, Jangoux 1982, Levin et al. 1987). Conformingly, in a preliminary survey at the study site, *A. pectinifera* (N \approx 1400) showed stomach-everting feeding behavior on (1) algae, (2) small macrobenthos and (3) detritus. Abundances of these foods were estimated for each sediment type in the following way. (1) The abundance of algae was seasonally estimated from summer 1995 to spring 1996 at 3 m depth at the 5 transects (Fig. 1). Presence and absence of the dominant algae (*Dictyopteris undulata*, *Eudarachne binghamiae*, *Hypnea charoides*, *Sargassum autumnale*, *Ulva pertusa*) were scored as 1 and 0, respectively, for each type of sediment in 0.25 m² quadrats thrown 4 to 12 times at each station. These scores were averaged for each station and then divided by the areas covered for each sediment type ('abundance index'). The abundance index for an alga and sediment type will increase with an increase in the number of quadrats containing the alga, or with a decrease in the area covered by the sed-

iments. (2) The density of the dominant small macrobenthos (Polychaeta: *Acanthopleura* sp., Gastropoda: *Mitrella bicincta*, Ascidiacea: *Styela plicata*) were estimated by counting them for each sediment type in the quadrats during the above-mentioned algal abundance survey. (3) The abundance of detritus was estimated from the frequency of stomach-everting behavior of *A. pectinifera*, assuming that the frequency of stomach-everting behavior would be higher where detritus is abundant. To calculate this frequency for each sediment, stomach-everting behavior of *A. pectinifera* occurring with no discernible food was seasonally observed at 1 to 9 m depths from autumn 1995 to summer 1996.

To investigate the availability of microhabitats on coarse sediments and fine sediments, hiding behavior of *Asterina pectinifera* was observed during the above-mentioned survey for starfish distribution. *A. pectinifera*, which hid in the sediments and thus were not visible from above, were counted by turning over coarse sediments and digging in fine sediments.

Translocation experiments. To investigate whether food and/or microhabitat in coarse sediments attract *A. pectinifera*, starfish were translocated with or without manipulated coarse sediments to the deeper area covered by fine sediments. For the experiments, 20 discontinuous 1 m² plots were arranged 5 m apart on the seabed at ~7 m depth between Transects A and D (Fig. 1). These plots were divided into 5 clusters in each of which 4 treatments (FM, FX, XM and XX) were arranged. On 17 March 1997, coarse sediments were translocated to FM with no manipulation (i.e. with Food and Microhabitat retained), and to FX after being broken into pieces of 3 to 4 cm² (i.e. with Food retained and microhabitat eXcluded), and to XM after being dried in the sun and washed, resulting in no organisms on the sediments except for polychaete tubes and barnacle shells (i.e. with food eXcluded and Microhabitat retained). No coarse sediment was translocated into XX (i.e. with food and microhabitat eXcluded). In each plot, 5 *A. pectinifera* randomly collected at 3 to 5 m depths were released with individual marks on 18 March 1997, resulting in a density (5.0 m⁻²) similar to that at 3 m depth (4.7 m⁻² in a preliminary survey). Then, 1, 2, 3, 4, and 9 d later, the number of marked *A. pectinifera* were recorded with their stomach-everting and hiding behaviors, although 1 of the 5 replicate clusters failed to be observed on Days 3 and 4 due to problems with SCUBA. The number of *A. pectinifera* was compared in 3 ways: between FM and XX, to compare attractiveness between coarse and fine sediments; between FM and FX or between XM and XX, to test for attractiveness to microhabitat in coarse sediment; and, between FM and XM or between FX and XX, to test for attractiveness to food on coarse sediments.

Statistical analysis. In the mark-recapture experiments, the direction of starfish movement was tested for randomness, using a Rayleigh test (Zar 1996). To do this test for each of Days 13 and 44, ~5 and ~15% of the found starfish with less clear marks were excluded, respectively, considering the misidentification rate in a laboratory experiment (Kurihara 1998). Additionally, 4 *Asterina pectinifera* that were found on both days were excluded from the analysis of Day 13, to avoid excessive Type I or II error from repeated measures (Underwood 1997).

In the translocation experiments, the number of starfish was compared by a 3-way orthogonal ANOVA without replication (treatments of food and microhabitat: fixed factors, Day: a random factor). For each treatment, a different plot of the 5 replicate plots was assigned to each of the 5 days to avoid repeated measures of the same plot. Data were log₁₀(n+1)-transformed, as they included zeros (Zar 1996).

The abundance of starfish or food could not be statistically compared between sediment types or depths, because it differed in both variances and sample sizes between treatments, thus violating assumptions for statistical testing (Underwood 1997).

RESULTS

Distribution pattern of *Asterina pectinifera*

At 3 and 5 m depths, *Asterina pectinifera* were found on 2 to 5 transects for each date. At 7 m depth, *A. pectinifera* were found on 0 to 3 transect(s) for each date. At 9 and 11 m depths, *A. pectinifera* were found on only 1 survey date on Transects A and B, respectively. The distribution pattern is well represented in Fig. 3, where mean density of *A. pectinifera* within each season was higher at 3 and 5 m depths than at greater depths, except for summer and spring on Transect A and for spring on Transect D.

This distribution pattern of *Asterina pectinifera* corresponds to the vertical change in the percentage cover of coarse sediments (Fig. 2). Coarse sediments, consisting of pebbles (mean ± SE length of the longest axis = 42.0 ± 2.1 mm; N = 76) and shells (60.2 ± 3.0 mm; N = 133), showed higher percentage cover at 3 and 5 m depths than at greater depths, except for Transect A. The correspondence between the starfish distribution and percentage cover suggests the aggregation of *A. pectinifera* on coarse sediments. This is reflected by the fact that within each of 60 combinations of transects, seasons and depths starfish density on coarse sediments was generally higher than (32 combinations) or equal to (23 combinations) the density on fine sediments (Table 2).

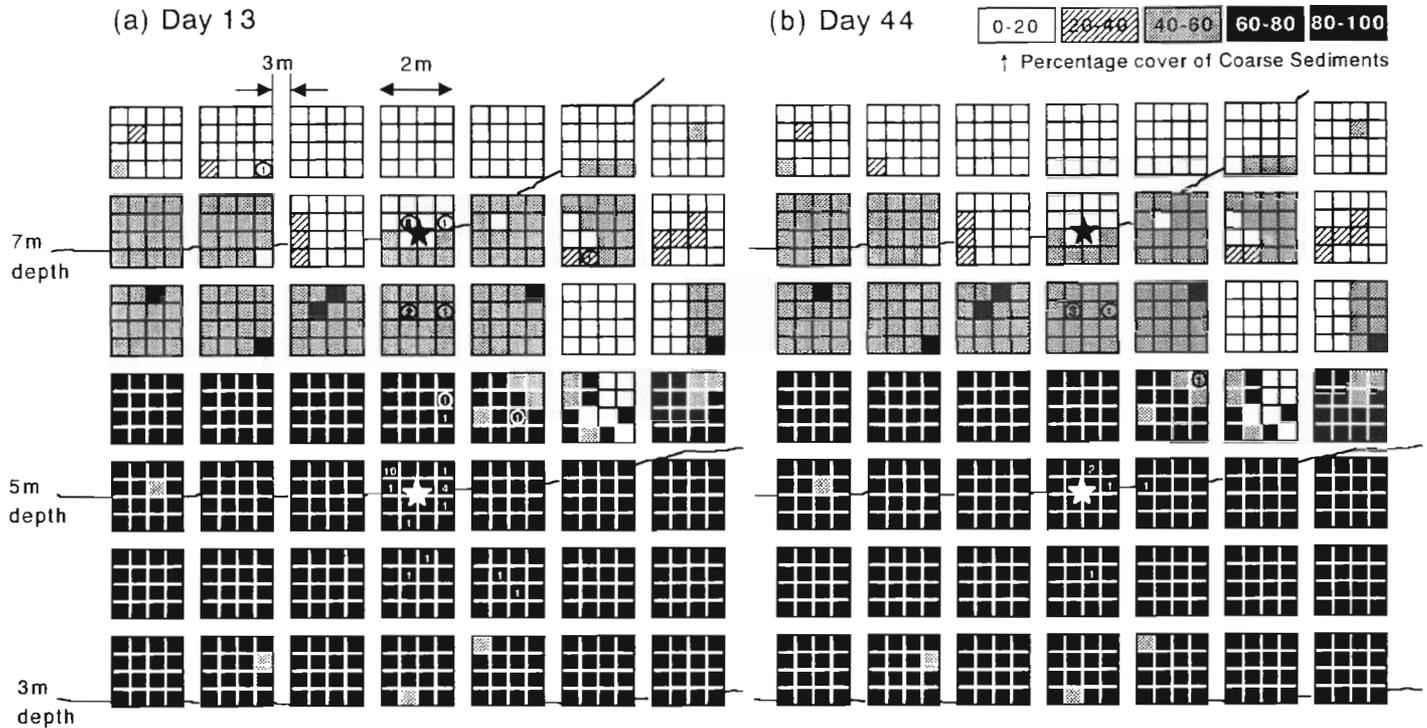

Fig. 4. *Asterina pectinifera*. Results of the mark-recapture experiments. Arrangement of 0.25 m² quadrats at ≥3 m depth is shown with positions of marked starfish (a: Day 13, b: Day 44). In each quadrat, percentage cover of coarse sediments is shown at 5 grades. Release points at 7 and 5 m depths are denoted by (★) and (☆). The numbers of recaptured starfish that were released at 7 and 5 m depth points are denoted by numerals with and without circle, respectively, excluding the starfish with unclear marks. Quadrats at <3 m depths are not given here, as the percentage cover of coarse sediments was constantly 80 to 100% and no marked starfish were found. Note that the scale of the figure differs among objects

Similar to Day 13, *A. pectinifera* released at 5 m moved a shorter distance than *A. pectinifera* at 7 m (mean ± SD distance: 2.5 ± 1.0 m and 6.0 ± 1.2 m, respectively). During the experiments, all marked *A. pectinifera* were found on a lump of coarse sediments (note that there were some lumps even in the 0.25 m² quadrats with 0 to 20% percentage cover of coarse sediments in Fig. 4).

Food abundance and frequency of hiding behavior

The small macrobenthos density, abundance index of algae, and stomach-everting rate, averaged for all transects and seasons (Table 3), were generally higher on coarse sediments than fine sediments. For each transect, season and species, the small macrobenthos density was higher by 0 to 6.9 m⁻² on coarse sediments than fine sediments (data not shown). This was also true for algae with an abundance index higher by 0 to 4.8 on coarse sediments, except for *Sargassum autumnale* on Transect D in winter. For each season, the stomach-everting rate was higher on coarse sediments (45.5 to 66.7%; N = 6 to 155) than fine sediments (0 to 50%; N = 1 to 8).

Hiding behavior was observed for 29.2% of 414 *Asterina pectinifera* on coarse sediments, while this behavior was not observed for the 70 *A. pectinifera* on fine sediments.

Table 3. Indices of food abundance (mean ± SE) with the number of observed individuals in parentheses. Stomach-everting rate indicates abundance of detritus. For the calculation procedure of each index see 'Materials and methods: Observations on food and microhabitat'

	Coarse sediment	Fine sediment
Abundance index of algae		
<i>Dictyopteria undulata</i>	0.15 ± 0.13	0.00 ± 0.00
<i>Eudarachne binghamiae</i>	0.41 ± 0.18	0.00 ± 0.00
<i>Hypnea charoides</i>	0.76 ± 0.32	0.00 ± 0.00

Density (m⁻²) of small macrobenthos		
<i>Acanthopleura</i> sp.	0.43 ± 0.32 (22)	0.00
<i>Mitrella bicincta</i>	1.77 ± 0.66 (93)	0.00
<i>Styela plicata</i>	0.08 ± 0.05 (26)	0.00
Stomach-everting rate (%) of <i>Asterina pectinifera</i>		
	58.8 (250)	26.3 (19)

Emigration of *Asterina pectinifera* from translocated plots

In the translocation experiments (Table 4), marked *Asterina pectinifera* remained in the experimental plots with food (FM and FX), and rapidly dispersed from those without food (XM and XX). The number of *A. pectinifera* was significantly larger in the plots with food than without food: $p = 0.02$, $F = (SS_{\text{Food}}/df_1)/(SS_{\text{Food} \times \text{Day}}/df_2) = (0.35/1)/(0.10/4)$. Unexpectedly, the number was slightly larger in the plots without microhabitats than with microhabitats, although not significantly: $p = 0.45$, $F = (SS_{\text{Microhabitat}}/df_1)/(SS_{\text{Microhabitat} \times \text{Day}}/df_2) = (0.011/1)/(0.064/4)$. The number of *A. pectinifera* was not significantly affected by the factor Day or interactions ($p > 0.05$). Stomach-everting behavior was found in 50.0% of *A. pectinifera* for FM (N = 22; Days 1 to 9 pooled) and 79.4% for FX (N = 34). Hiding behavior was found only for FM (31.8%; N = 22).

Table 4. *Asterina pectinifera*. Mean \pm SE number of starfish in the translocation experiments. Starfish number is presented for each plot where coarse sediments were translocated with no manipulation (FM), after removing microhabitats (FX) and after removing food (XM), or not translocated (XX). See 'Results' for statistical tests

Day	Number of starfish			
	FM	FX	XM	XX
1	1.6 \pm 0.40	1.6 \pm 0.68	0.0	0.0
2	1.4 \pm 0.51	1.8 \pm 0.58	0.0	0.0
3	0.75 \pm 0.25	2.0 \pm 0.41	0.0	0.0
4	0.50 \pm 0.50	1.5 \pm 0.29	0.0	0.0
9	0.40 \pm 0.24	0.60 \pm 0.24	0.0	0.0

DISCUSSION

Effects of coarse sediments on the vertical distribution of *Asterina pectinifera*

Asterina pectinifera was more abundant at 3 to 5 m depths than at greater depths, which was at least partly due to the presence of coarse sediments at 3 to 5 m depths. This is supported by the following results: correspondence between their vertical distribution patterns at ≥ 3 m depth (Figs. 2 & 3); higher density of *A. pectinifera* on coarse sediments (Table 2); movement of marked *A. pectinifera* toward coarse sediments in the mark-recapture experiments (Fig. 4); lower emigration rate of *A. pectinifera* from coarse sediments than from fine sediments in the translocation experiments (compare FM and XX in Table 4).

Although predators, competitors and water temperature also have been suggested to decrease the density

of starfish with increasing depth (Mauzey et al. 1968, Gage et al. 1984, Stevenson 1992), none are considered to vertically change the density of *Asterina pectinifera* at ≥ 3 m depth in the present study site. *Luidia quinaria*, a possible predator of *A. pectinifera*, was found at a low density (Table 1), and appears to eat few *A. pectinifera*: only one *L. quinaria* among 103 individuals observed had *A. pectinifera* (or perhaps another starfish) in its stomach, and the other *L. quinaria* mainly had bivalves and/or echinoids (Kurihara pers. obs.). Other predators such as *Pleuroploca trapezium* (Okutani 1994) and other starfish of the family Luidiidae (Jangoux 1982) were not found. Although possible competitors such as *Omphalius* sp., *Lunella coronata coreensis*, *Asterina batheri*, and *Astropecten polyacanthus* were observed at high density (Table 1), they were less abundant at ≥ 7 m depth than at ≤ 5 m depth, which does not appear to cause lower density of *A. pectinifera* at ≥ 7 m depth. The annual mean water temperature at the present study site differs by $< 2^\circ\text{C}$ between 3 to 5 m and 10 m depths (Tamura 1992), which is unlikely to affect the density of *A. pectinifera*, considering the large spatial variation in water temperature ($> 10^\circ\text{C}$) over the geographical range of *A. pectinifera* (Kurihara 1996).

In contrast with the density change from 3–5 m to ≥ 7 m depths, fluctuations among seasons, among transects, and between 1 m and 3 to 5 m depths (Fig. 3) appear to be unrelated to sediment type. The low density in autumn is likely to be due to fluctuations in the mortality rate. This is supported by observations that white *Asterina pectinifera* (i.e. dying specimens) were found at the study site with a higher frequency during autumn (~30%) than spring (~9%). The cause of the extremely low density on Transect D is not clear. The lower density at 1 m depth might have been caused by competition for food with gastropods which were abundant there (Table 1). Such exploitative competition for food between starfish and gastropods has been reported by Branch & Branch (1980). Mechanisms of these density fluctuations among seasons, transects and depths at < 3 m require further examination.

Role of coarse sediments

Availability of microhabitats on coarse sediments may not increase density of *Asterina pectinifera* at ≥ 3 m depth. This is supported by the translocation experiments (Table 4) in which, unexpectedly, *A. pectinifera* stayed with slightly greater frequency in the plots without microhabitats than those with microhabitats. Although microhabitats provide some benthic animals with shelters from wave action and predators (e.g. Lubchenco 1980), these appear to be unimportant

for *A. pectinifera* at ≥ 3 m depth at the present study site. This is presumably because at the study site wave action is weak and possible predators are rare (Table 1). The greater number of *A. pectinifera* without microhabitats than with microhabitats is perhaps ascribable to odor emitted by injured sessile organisms on the experimentally broken coarse sediments (see Moore & Lepper 1997 for attractivity of odor to starfish)

In contrast with microhabitat, abundant food in coarse sediments seems to increase the density of *Asterina pectinifera* (Table 3). This is supported by the translocation experiments in which marked *A. pectinifera*, frequently showing stomach-everting behavior, stayed only in the experimental plots containing food (Table 4). Food in some specific sediments and the density of some other starfishes are also closely related, as is suggested for *Astropecten latespinosus* and organic matter in sand (Nojima 1989), and for Atlantic subtidal starfishes and mussels on boulders (Himmelman & Dutil 1991).

In summary, the density of *Asterina pectinifera* decreases from 3–5 m to ≥ 7 m depths, at least partly because coarse sediments with abundant food decrease in the deeper zone. In the intertidal zone, the effect of sediments on the vertical distribution of benthic organisms has been reported only for a few species (Underwood & Barrett 1990, Iwasaki 1995b). In the subtidal zone, however, because sediment type often varies among depths, such phenomena can be observed more generally and should be experimentally studied in the future.
