

# Response of Soft-Bottom Benthos to Annual Catastrophic Disturbance in a South Florida Estuary\*

S. L. Santos\*\* and J. L. Simon

Department of Biology, University of South Florida, Tampa, Florida 33620, USA

**ABSTRACT:** A portion of Hillsborough Bay (Tampa, Florida, USA), part of the Tampa Bay estuary, undergoes annual summer defaunation, presumably due to hypoxia. Dissolved oxygen levels are very low ( $< 1.0 \text{ mg l}^{-1}$ ) at the times of the defaunations. In the ensuing period between defaunations, recolonization occurs. Monthly samples for 42 consecutive months were collected by SCUBA-diver-operated, hand-held PVC cores and screened through a 0.5 mm sieve. Eight species, *Mysella planulata*, *Ampelisca abdita*, *Streblospio benedicti*, *Grandidierella bonnieroides*, *Mulinia lateralis*, *Mediomastus californiensis*, *Cyclaspis* sp. and *Nereis succinea* were numerically dominant, accounting for more than 95 % of the total density during the entire period. These 8 species are all classified as *r*-strategists and utilize several dispersal mechanisms to attain large populations rapidly. Circumstantial evidence is presented which indicates that *Ampelisca abdita*, although classified as an *r*-strategist, may be an effective interference competitor

## INTRODUCTION

Recolonization patterns of marine soft-bottom benthos following disturbance have been examined from the viewpoint of community establishment (Brunswig et al., 1976; Dauer and Simon, 1976; Simon and Dauer, 1977; McCall, 1977; Santos and Simon, 1980), succession (Bagge, 1969; Leppakowski, 1969; Pearson, 1975; Rosenberg, 1973; 1974, 1976, 1977; Pearson and Rosenberg, 1978; Santos and Bloom, in prep.), and stability (Peterson, 1975; Conner, 1977; Gray 1977; Santos and Bloom, in prep.). In most instances however, the scope of the investigations has followed isolated disturbances and moreover, the severity of the disturbances has not approached catastrophic magnitudes (catastrophic is defined as the level of disturbance that causes extirpation of the organisms from the area investigated).

Because most catastrophic events are aperiodic, at least on an ecological time frame, and hence unpre-

dictable, investigations on their effects have been of a limited or 'one shot' nature, and thus unrepeatable. A few studies in estuarine systems (Tenore, 1972; Watling, 1975; Holland et al., 1977) noted annual catastrophic cycles, but because these were not the focal point of the studies, they were not treated in detail. Yet areas that undergo periodic catastrophic disturbance (providing the frequency of the disturbance is low enough to allow growth and reproduction of the colonizing organisms) lend themselves to the examination of such ephemeral community parameters as succession and stability and also of adaptive strategies of the colonizing species. In this paper we describe the dynamics of the numerically dominant infauna in response to annual catastrophic disturbance in a South Florida estuary.

## METHODS AND MATERIALS

The study site (Fig. 1) is located about 50 m ESE from the Ballast Point pier on the western side of Hillsborough Bay, Tampa (Florida, USA) at 27°53'15''N and 82°28'35''W. Depth ranges from 4-5 m, depending on tidal conditions. Tidal movement is slight, ~ 0.5 knots. Sediments are composed mostly of fine particles (mean percent of silt/clay = 10.34).

During the period February 1975 to July 1978, monthly samples (with a single exception) were collected with SCUBA-diver-operated, hand-held PVC cores (inside diameter = 7.62 cm, surface area = 45.60 cm<sup>2</sup>) to a depth of 15 cm. Sixteen cores were taken initially; species saturation curves (Holme, 1953) were generated and drawn by the computer program SPAREA (Bloom et al., 1977). As each of the curve generations demonstrated that the asymptote was reached by the ninth core, 10 cores were taken to insure an adequate sample size at subsequent collections. All samples were sieved through a 0.5 mm mesh screen. The portion retained was narcotized in a

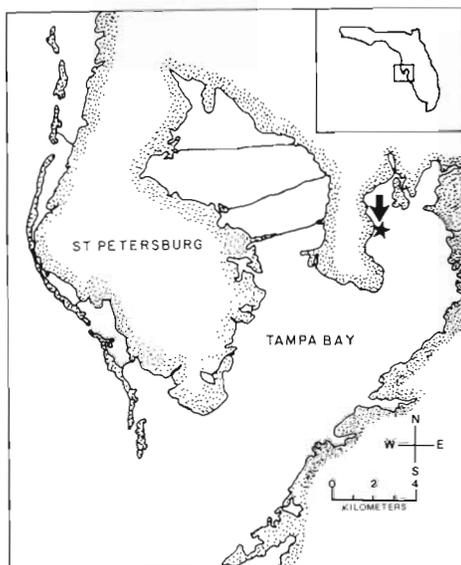

Fig. 1. Location of study area in Hillsborough Bay, Tampa, Florida, USA. Arrow denotes sample site

0.15 % solution of propylene phenoxetol (McKay and Hartzband, 1970) and fixed in 10 % formalin to which rose bengal had been added (100 mg l<sup>-1</sup>) (Mason and Yevich, 1967). All benthic macrofauna were sorted from the sediment, identified to the lowest practical taxon and enumerated. Faunal counts from each core were processed through the computer program DATPUN (Bloom et al., 1977) to obtain density values on a per-square-meter basis.

Monthly biomass was determined by the ash-free dry weight method (Crisp, 1971; Paine, 1971); specimens from all cores were pooled before processing. All specimens were dried at 60 °C for at least 24 h, then ashed in a muffle furnace at 550 °C for 4 h and brought to constant weight. Biomass was calculated as the difference in weight before and after ignition.

Sediment samples were taken monthly, beginning July 1977, to determine particle size distribution and total organic content. Samples were wet-sieved

through a Wentworth series of screens and dried at 60 °C. After bringing to constant weight, each fraction was weighed and cumulative percentages in phi units plotted (Krumbein, 1936). Mean phi and sorting coefficients were determined by the computer program SEDANA (Bloom et al., 1977) according to the formulae of Inman (1952). Total sediment organic carbon was also determined by the ash-free dry weight method (Byers et al., 1978). Differences in monthly sediments were tested for by a randomized complete block analysis of variance (rcbANOVA), where times (monthly samples) were considered treatments and sorting coefficient, mean phi and percent silt/clay values were considered blocks; a probability level of  $\alpha = 0.05$  was used.

All computer programs were written in FORTRAN IV and run on an IBM 370 computer at the University of South Florida Computer Research Center.

Temperature, dissolved oxygen and salinity measurements were made monthly by the Hillsborough County Environmental Protection Commission. All measurements were made in the field with a Hydrolab Surveyor, Model 6-D, that had been calibrated to standards before each use.

## RESULTS

Temperatures ranged from 9°–31 °C, dissolved oxygen from 0.4–9.6 mg l<sup>-1</sup> and salinity from 7–30 ‰ (Fig. 2). The values corresponding to the defaunation periods are given in Table 1. Analysis of variance of mean phi, sorting coefficient and percent silt/clay values (Table 2) showed no significant differences between months.

A total of 80 species was present during the study period (see Appendix). The polychaetes were the dominant taxon, accounting for 33 % of the total species composition followed by the amphipods and bivalves, respectively (Table 3). The number of species, total density (# m<sup>-2</sup>) and biomass (g dry weight m<sup>-2</sup>) ranged from 0–29, 0–216,577 and 0–27, respectively (Fig. 3). Annual cycles following the defaunations were similar in 1975 and 1976, and characterized by: a few months to recover, rapid rise to high values, an abrupt crash to zero followed by a few months of recovery and return to high values. In 1977 the pattern differed slightly. The required time to attain peak values was about the same but the crash was gradual, requiring >2 months (Fig. 3B). In all three cycles recolonization was apparent within 1 month following the defaunation.

Eight species cumulatively accounted for 95.69 % of the total density during the entire study (Table 4); these species will be referred to as core species. With

the exception of the first or second sampling periods immediately following a die-off (the third after the 1976 die-off), some members of the core group were always dominant at each sampling period (Table 5). Densities of these 8 individual species throughout the study are presented in Figure 4. Their occurrences are summarized below.

*Mysella planulata* (Stimpson 1851) — *Mysella* (Fig. dominant species for the first 7 months of the study (Table 5). After the 1975 die-off, it reappeared within 4 months and attained a density of 72,000 m<sup>-2</sup> just before the 1976 die-off. Thereafter it again became dominant for a few months, disappeared for 2 months and was on the increase when the 1977 die-off occurred; densities were always < 2000 m<sup>-2</sup>. After the 1977 die-off, it never occurred at densities high enough to be included in the top five rankings; densities were maximally from 1000 to 4000 m<sup>-2</sup>.

Table 1 Bottom water: environmental parameter values during defaunation periods

Parameter	1975	1976	1977
Temperature (°C)	29.0	24	27
Dissolved oxygen (mg l <sup>-1</sup> )	0.4	0.5	0.6
Salinity (‰)	19.0	18.0	28.0

*Ampelisca abdita* Mills 1964 — *Ampelisca* (Fig. 4B) is a tube-dwelling ampeliscid amphipod that occurred in very high densities during the first 2 years of the study (to 110,000 m<sup>-2</sup>). After the 1975 die-off, it reappeared within 2 months and by the sixth month attained top rank (Table 5). It reappeared 8 months after the 1976 die-off and again increased rapidly. It was top ranked for 2 months until the 1977 die-off. Subsequently it was virtually absent.

*Streblospio benedicti* Webster 1879 — *Streblospio*

Table 2. Mean phi, sorting coefficients and percent silt/clay during period July 1977-July 1978

Time	Mean phi	Sorting coefficient	Percent silt/clay

(Fig. 4C), a small tube-dwelling spionid polychaete, was included in the top five rankings only three times before the 1976 die-off, and after the 1976 die-off, densities increased only slightly. However, after the 1977 die-off, it attained densities of up to 98,000 m<sup>-2</sup>. *Grandidierella bonnieroides* Stephenson 1949 — *Grandidierella* (Fig. 4D) is an aorid amphipod that co-occurred with *Ampelisca* in high densities (to 96,000 m<sup>-2</sup>) during the first 7 months of the study. After the 1975 die-off, it took 8 months to reoccur. Since the 1976 die-off, it was not present in appreciable numbers (< 40 m<sup>-2</sup>).

*Mulinia lateralis* (Say 1822) — *Mulinia* (Fig. 4E), a mactrid bivalve, occurred sparsely (< 400 m<sup>-2</sup>) prior to the 1975 die-off. The third month after the die-off, it reached top rank and remained in the upper five until the 1976 die-off (Table 5). It took 4 months for *Mulinia* to regain ranking in the top five where it remained until the 1977 die-off. Four months later, it reappeared and remained constant, but at reduced numbers, until the 1978 die-off.

*Mediomastus californiensis* Hartman 1944 — *Mediomastus* (Fig. 4F), a small capitellid polychaete, was not present in the study area until after the 1977 die-off. It

Table 4. Density, percent composition and cumulative percent of the 8 numerically dominant species of benthic macroinvertebrate infauna in Hillsborough Bay, February 1975 to July 1978

Species	$\Sigma$ Density (# m <sup>-2</sup> )	Percent	Cumulative percent
<i>Ampelisca abdita</i>	786,217	42.93	42.93
<i>Mysella planulata</i>	549,982	30.03	72.95
<i>Streblospio benedicti</i>	198,670	10.85	83.80
<i>Mulinia lateralis</i>	74,022	4.04	87.84
<i>Mediomastus californiensis</i>	39,610	2.16	90.01
<i>Cyclaspis</i> sp.	35,330	1.93	91.94
<i>Nereis succinea</i>	35,230	1.92	93.86
<i>Grandidierella bonnieroides</i>	33,600	1.84	95.69

became dominant after 4 months and remained so for 5 months, after which it virtually disappeared.

*Cyclaspis* sp. — *Cyclaspis* (Fig. 4G) is a small bodotriid cumacean. High densities (11,000 m<sup>-2</sup>) were not attained until 1976. After 4 months it disappeared and did not reappear until the middle of 1977. *Cyclaspis* was present in the top five rankings for only 1 month after the 1977 die-off.

*Nereis succinea* Frey and Leuckart 1847 — *Nereis* (Fig. 4H), a nereid polychaete, showed little variation in maximum density throughout the study (1000 to 3000 m<sup>-2</sup>). The reason for the change of rankings in Table 5 is attributable to the changes in densities of other species rather than large fluctuations in the density of *Nereis*.

## DISCUSSION AND CONCLUSIONS

The actual causative agent of the defaunation is unknown; however, the extremely low dissolved oxygen levels which coincided with the actual die-off appear to be the prime suspect. Because the bottom of the study area is impossible to define at times due to its flocculent nature, the measurements were probably made above the actual sediment/water interface and are in all likelihood overestimates of conditions at the bottom.

Because the environmental parameters varied widely, even to catastrophic magnitudes, the study area can be regarded as structured by physical rather than biological forces (*sensu* Sanders, 1969). Although no significant differences in sedimentary parameters existed among the sampling periods, it is always possible that subtle changes in the structure of the sediment may affect settling larval organisms. For example, changes in silt/clay content may alter the dominant trophic type of the community (Sanders, 1958).

Because of the strong influence of physical factors,

Table 5. Ranking (1–5) of the 8 numerically dominant macroinvertebrate infaunal species in Hillsborough Bay, February 1975 to July 1978. X: month of die-off; \*: month in which none of the major species were dominant; —: no collection

one would expect the taxa to display life-history strategies tending toward *r*-selection (Grassle and Grassle, 1974; McCall, 1977). Briefly stated, *r*-selected species are opportunistic, whereas *K*-selected species are equilibrium species (for a more detailed view of these ideas, see MacArthur and Wilson, 1967; Pianka, 1970, 1974). Of the 80 taxa present at sometime during the study, the top ranked 8 (core) species, comprising > 95 % of the total density, have been classified by various authors (Grassle and Grassle, 1974; McCall, 1977; Rhoads et al., 1978) as *r*-selected. The remainder (72 taxa accounting for < 5 % of the density) may be divided into 2 groups, those occurring 10 % or less of the time and those occurring more than 10 % of the time. The first group may be considered as accidentally occurring and are eliminated from further discussion. Of the remaining 33 taxa, occurrences at sampling periods vary, and although they may numerically dominate at some sampling periods (e.g. Oct. 1976, Table 5) densities are extremely low (< 66 m<sup>-2</sup>). The locations of most of these taxa on the *r*-*K* continuum are unknown. Some of these taxa are capable of initially recolonizing the defaunated sediment (Santos and Simon in press) but are unable to attain high densities. Rhoads et al. (1978) suggest that although equilibrium species are capable of initial recolonization of marine soft-bottom environments, they cannot attain high densities until a 'microbial' garden has developed on the sediment particles. We do not feel that this is responsible in the present study because bacteria are present in the sediment throughout a cycle (L. Buckman, personal communication).

In the studies by Rosenberg (1972, 1973), Grassle and Grassle (1974), McCall (1977) and Rhoads et al. (1978), as colonization proceeded, the density of opportunistic species decreased while the density of equilibrium species increased. A decrease of *r*-selected species densities and increase of *K*-selected species densities did not occur in the present study. The 8 above-mentioned core species never relinquished their 'hold' on density dominance. As the above-cited studies were performed in areas that did not undergo periodic natural defaunations, environmental pressures and conditions are most likely different from Hillsborough Bay. Wolff et al. (1977), studying recolonization in a shallow embayment of the North Sea, also did not observe a shift from *r*- to *K*-selected species density dominance. They attribute this lack to severe winter storms, which cause local defaunations in the bay creating empty patches, allowing the *r*-selected species to persist.

In the present study, the basic response of the organisms to the newly available habitat is repopulation by many species (15–29) with 1–6 species dominant at different times during the cycle. Organisms which are

able to attain high densities rapidly (*r*-selected species) are usually adapted for (1) some type of brood protection and (2) good dispersal abilities as larvae, juveniles or adults. Of the core group, the only species that have not been observed brooding young are *Nereis succinea* and *Mulinia lateralis* (personal observation). All, except *Mysella planulata*, from the study also appear to have a pelagic dispersal mechanism either as adults or larvae. This observation is in contrast to the findings of Franz (1973) and Ockelmann and Muus (1978). They found that *M. planulata* from Long Island Sound (Franz, 1973) and *M. bidentata* from the northern Oresund (Ockelmann and Muus, 1978) brooded their young only to the veliger stage. These were then released into the water column and assumed a planktotrophic development. *M. planulata* from the present study were observed releasing fully developed juveniles. *M. sovaliki* from Alaska has also been reported to brood juveniles until they are ready to assume a benthic existence (Ockelmann and Muus, 1978). Some species of spionid and cirratulid polychaetes (George, 1967; Simon, 1968; Woodwick, 1977) have been observed to produce two types of larvae, free-swimming for long range dispersal and benthic for local dispersal. Whether *Mysella* or any other species from this study is capable of this behavior is unknown. If the *M. planulata* from the present study did not produce a pelagic larval stage, this could account for the longer recovery period of this species. *Ampelisca*, on the other hand, has both an adult and juvenile pelagic dispersal mechanism and broods its young. Because of its tendency to migrate and settle *en masse* (Mills, 1967), it could rapidly attain high densities. The early maturation of *Streblospio* larvae, their brooding behavior and their ability to disperse pelagically as late stage larvae most likely is responsible for their success. *Grandidierella* and *Cyclaspis* follow the same strategy as *Ampelisca*. *Nereis* is capable of both adult and larval pelagic dispersion while *Mulinia* has only a larval type. Egg masses of *Mediomastus* have been observed in their tubes but not enough of their biology has been observed to allow supposition.

In the present study, not all core species were present each year, and of those that were, densities fluctuated widely. The two dominant species during the first two cycles, *Ampelisca* and *Mysella*, either did not appear during the third (1977–78) cycle or appeared in such reduced numbers that a ranking in the top five was never attained. *Streblospio*, which prior to the 1977 die-off had been present at low densities at scattered intervals, became dominant for the entire 1977–78 cycle. Simultaneous to this, *Mediomastus*, which had been absent, appeared and attained very high densities.

The loss of *Ampelisca* after the 1977 die-off is unexplainable. The rapid increase of *Streblospio* and *Mediomastus*, however, may be related to the disappearance of *Ampelisca*. Although no experimental data verify this possibility, circumstantial evidence is strong enough to allow speculation. *Streblospio* is a small (5–15 mm long, 1 mm wide) tube-building polychaete that resides in the upper 1–2 cm of the substratum. If its densities are high, mats are produced on the surface. In some cases, one of us (SLS) has lifted the entire mat from the sediment similar to a piece of sod. The composition of the mat is such that it soon breaks apart. *Ampelisca* is also a tube-builder, constructing a larger tube extending deeper into the sediment. *Ampelisca* lie on their backs and feed by thrashing the antennae across the sediment-water interface, causing detritus to be suspended (Mills, 1967). They then filter the detritus from the water. *Ampelisca* also periodically vacate their tubes and swim *en masse* in the water column (Mills, 1967). Later they settle, build tubes and resume feeding. Possibly *Ampelisca* limits *Streblospio* populations in two ways. First, if *Streblospio* already are established, the settlement, tube-building and feeding behavior of *Ampelisca* would disrupt the *Streblospio* tubes. Secondly, once *Ampelisca* is established, feeding behavior would prevent successful recruitment of juvenile *Streblospio* (and perhaps other species as well).

Once the conditions which caused the defaunation abate, recolonization proceeds rapidly. Regardless of whether the initial recolonization is by members of the core group or any of the other taxa, the subsequent colonization sequence appears stochastic (Santos, 1979). However, due to the dispersal and brooding behavior, once all or some of the core species become established, they numerically dominate until the next defaunation. The conditions which allow the *r*-selected species to numerically dominate throughout the year, even in the presence of species that are probably more *K*-selected are unknown. One of the proposed hallmarks of being a good opportunistic species is a lack of competitive ability (Pianka, 1974), yet as suggested by *Ampelisca*, this may be an overgeneralization. In fact, *Ampelisca* may be a very effective interference competitor.

## APPENDIX

Species present during study period (\* denotes present at only one sampling period):

### Cnidaria

\**Paranthus rapiformis* LeSueur 1817

*Edwardsia* sp.

### Platyhelminthes

*Stylochus* sp.

### Rhynchocoela

unidentified rhynchocoels

### Polychaeta

*Sthenelais boa* (Johnston 1839)

*Eteone heteropoda* Hartman 1951

\**Eumida sanguinea* (Oersted 1853)

*Phyllodoce arenae* Webster 1879

*Gyptis vittata* Webster and Benedict 1887

*Parahesion luteola* (Webster 1880)

\**Brania wellfleetensis* Pettibone 1956

*Nereis succinea* Frey and Leuckhart 1847

*Stenoninereis martini* Wesenburg-Lund 1958

*Glycera americana* Leidy 1855

*Glycinde solitaria* (Webster 1879)

*Diopatra cuprea* (Bosc 1802)

*Schistomeringos rudolphi* (Delle Chiaje 1828)

*Minuspio cirrifera* (Wiren 1883)

*Paraprionospio pinnata* (Ehlers 1901)

*Polydora ligni* Webster 1879

*Polydora socialis* (Schmarda 1961)

\**Polydora websteri* Hartman 1943

*Pseudopolydora* sp.

*Streblospio benedicti* Webster 1879

\**Tharyx* sp.

*Capitella capitata* (Fabricius 1780)

\**Capitellides jonesi* Hartman 1959

*Heteromastus filiformis* (Claparede 1864)

*Mediomastus californiensis* Hartman 1944

*Pectinaria gouldii* (Verrill 1873)

*Melinna maculata* Webster 1879

### Oligochaeta

unidentified oligochaetes

### Pelcypoda

*Amygdalum papyria* (Conrad 1846)

*Anadara transversa* (Say 1822)

\**Cyrtopleura costata* Linnaeus 1758

*Mulinia lateralis* (Say 1822)

*Corbula caribaea* Orbigny 1842

*Sphenia antillensis* Dall and Simpson 1901

\**Periploma margaritaceum* (Lamarck 1801)

*Mysella planulata* (Stimpson 1851)

*Semele proficua* (Pulteney 1767)

*Macoma tenta* (Say 1834)

*Tellina versicolor* DeKay 1843

\**Mercenaria campechiensis* (Gmelin 1791)

### Gastropoda

unidentified gastropod

*Cochliolepis* sp.

\**Anachis obesa* (C. B. Adams 1845)

*Marginella apicina* Menke 1828

*Acteocina canaliculata* (Say 1822)

*Acteon punctostriatus* (C. B. Adams 1840)

\**Haminoea succinea* (Conrad 1846)

*Odostomia* sp.

*Turbonilla* sp.

**Amphipoda**

**Acknowledgements.** We would like to thank D. Carpenter, E. Pinson, C. Stiles-Lewis, J. Murdoch, F. Reeves, R. Mattson, and R. Kittrell for assistance with the SCUBA diving and other field work. Dr. S. A. Bloom provided the computer programs. R. Wilkens supplied the environmental parameter values. K. Mooren assisted in all aspects of this study. Dr. R. W. Virnstein critically reviewed an earlier draft of this manuscript. Support for writing was provided by a postdoctoral fellowship (SLS) from Harbor Branch Institution. This research was partially funded by Florida Sea Grant R/EM-7 awarded to JLS.
