**ABSTRACT:** Resilience is an increasingly important aspect of ecological theory and management, yet natural variation in resilience remains poorly understood. I quantified spatial variation in resilience by calculating recovery rates and trajectories in the rocky intertidal ecosystem across biogeographic regions along the coast of California in 4 intertidal assemblages dominated by taxa with contrasting dispersal distances, lifespans, and trophic positions. Here I have shown that resilience itself can vary dramatically across taxa and biogeographic regions and that this variation may be understood in the context of the life history characteristics, the ecology of the disturbed taxa, and the pathway by which recovery occurs. Overall, the barnacle and turf algal assemblages displayed the fastest recovery rates, while the mussel and rockweed assemblages showed recovery rates that were the slowest and most variable. Significant variation in both recovery rates and trajectories across regions in the invertebrate-dominated assemblages indicated that regional differences in the delivery of propagules were potential drivers in differences in recovery rates for these taxa. By contrast, regionally varying recovery trajectories, but not recovery rates, in the algal-dominated assemblages suggested difference in timing of key events driving the recovery process. The effect of disturbance magnitude on recovery rates was consistent across regions for the mussel and rockweed assemblages, but in the barnacle and turf algal assemblages, the effect of disturbance size differed across regions, indicating variability in processes that drive edge effects. In all 4 assemblages, geographic differences in recovery trajectories outweighed differences across disturbance sizes.

**KEY WORDS:** Resilience · Recovery · Succession · Intertidal · *Chthamalus* · *Mytilus* · *Endocladia* · *Silvetia*

## INTRODUCTION

Understanding the manner in which communities respond to perturbations is one of the most fundamental goals of ecology (Connell & Slatyer 1977, Bazzaz 1979). Because both natural and anthropogenic disturbances can result in loss of biomass, understanding the process of recovery after a disturbance is both an important component of understanding how communities function as well effectively managing natural resources. The rate of recovery after such perturbations can be thought of as 'resilience' (Con-

nell & Sousa 1983), and while there has been much theoretical (e.g. Holling 1973) and practical (e.g. Leslie & Kingzig 2007) attention to this concept, experimental explorations of resilience are rare (but see Allison 2004, Viejo 2009). Resilience is often treated as a feature of ecosystems that is desirable from a management perspective (e.g. Elmqvist et al. 2003) and relatively static in the absence of human perturbations (e.g. van Nes & Scheffer 2007), a perspective that overlooks the potential importance of natural variation in resilience. Such variation will be driven in part by the life history characteristics of the

\*Email: tish.conway-cranos@noaa.gov

organisms present at a given location (e.g. lifespan and dispersal distance) and in part by location-specific factors that govern the delivery and survival of new propagules, resulting in a geographically varying mosaic of underlying recovery potential. As such, the recovery potential of a given location is thus likely to arise from both species-specific qualities and geographically or spatially varying ones.

Ecological recovery from natural or anthropogenic disturbances can be understood in (at least) 2 complementary ways. First, the timeframe of convergence with an undisturbed condition can be estimated by determining the 'recovery rate', or the amount of time it takes for ecological recovery to occur. Recovery itself can be defined as a statistical value expressed as some *a priori* similarity to the undisturbed condition, which also may change over time. Second, recovery can be thought of as an 'ecological trajectory', the temporal progress of ecological states prior to defined recovery. This can be considered the ecological path taken between disturbance and recovery. Differences in such paths reflect varying contributions and timing of different ecological mechanisms directing the successional process. While recent studies have improved our understanding of recovery and the successional mechanisms that can govern this process (e.g. Crain et al. 2008, Lebrija-Trejos et al. 2010), our understanding of the extent to which recovery rates and trajectories may vary across taxa and spatial locations remains limited (but see Kinnetic Laboratories 1992, Bertness et al. 2002, Petraitis & Dudgeon 2005).

Empirical work in both terrestrial (e.g. Phillips & Shure 1990, Hubbell et al. 1999, Dietze & Clark 2008) and marine (e.g. Paine & Levin 1981, Farrell 1991, Petraitis & Dudgeon 1999, Cervin et al. 2004) systems has shown that community processes and rates of recovery differ among disturbed patches of different sizes, often in seemingly inconsistent ways. In part, this is because the surrounding edge habitat may have strong and varying effects on new recruits. If organisms in intact edge habitat have a negative impact on incoming propagules or early life history stages, large disturbances may be expected to recover more quickly than small ones, since the center of such disturbances would represent a refuge from negative edge effects. Negative edge effects can be the result of shading by intact adjacent canopy species (Bazzaz 1979), from algal whiplash (Jenkins et al. 1999, Cervin et al. 2004), predation of larvae by adults (Young & Gotelli 1988), or grazing by herbivores that take refuge in undisturbed habitat (Sousa 1984). Conversely, surrounding biota may

have a positive effect on recovering propagules through amelioration of physiological conditions (Bertness & Shumway 1993) or gregarious settlement (Raimondi 1990). In such cases, smaller disturbances would be expected to exhibit faster recovery rates than large ones. Thus, insights can be obtained into the processes responsible for driving variation in recovery rates and trajectories by examining community response to disturbances of varying sizes. Typically, studies on the effects of disturbance size on recovery use a small number (2 to 3) of contrasting patch sizes (Sousa 1984, Farrell 1989, Bertness et al. 2002), which permits comparing dynamics between different disturbance sizes but does not permit characterizing recovery with respect to disturbance size. Knowing the shape of the relationship between disturbance size and recovery rate is consequently better addressed if a gradient of potential disturbance sizes is examined.

There is growing awareness among ecologists of the importance of understanding the extent to which community dynamics are influenced by factors that vary predictably with spatial or geographic location (Underwood 2000, Menge et al. 2004, Coleman et al. 2006, Burrows et al. 2009). However, much of our current understanding of many important ecological processes come from experiments conducted within relatively limited spatial scales (e.g. Paine 1966, Tilman 1985). Those studies that have investigated succession across more broad geographic scales in both marine (e.g. Chapman & Underwood 1998, Dudgeon & Petraitis 2001, Foster et al. 2003) and terrestrial (e.g. Dietze & Clark 2008) systems have demonstrated that the recovery process can vary dramatically in space and that the relative importance of the mechanisms driving recovery can change over spatial scales in response to geographic variation in propagule availability, consumer pressure, abiotic factors, or some combination thereof. However, because of the data-intensive nature of studying rules of assembly, studies examining recovery or succession often sacrifice a broad-scale approach for a more detailed understanding of succession at a location or within a particular type of ecological community. In marine systems, there may be significant variation in recovery rates and trajectories in response to variation in larval supply, nutrient delivery via upwelling, temperature, or variation in consumer pressure (Connolly et al. 2001, Menge et al. 2004, Coleman et al. 2006, Broitman et al. 2008). These location-specific suites of factors are likely to favor particular traits of recovering species. Because many intertidal species occur throughout much of the west coast of the USA,

despite dramatic abiotic and biotic differences across this range (Blanchette et al. 2008), the California current ecosystem provides a unique opportunity to examine recovery rates across a common suite of species, yet displays meaningful variation in abiotic and biotic factors that could lead to different recovery dynamics in different locations. While there is agreement that processes that vary on broad spatial scales are likely to be important in determining the outcome of succession (e.g. Chapman & Underwood 1998, Dudgeon & Petraitis 2001, Foster et al. 2003), this possibility has been rarely explored experimentally across multiple intertidal assemblages (but see Kinnetic Laboratories 1992). Here, I demonstrate a pattern of community-specific spatial variation in ecological resilience by quantifying recovery rates and trajectories in 4 different intertidal assemblages across a broad spatial scale on the west coast of the United States.

#### Background: study system

The west coast of the USA has been remarkably well characterized with respect to geographic patterns in water temperature, recruitment (e.g. Broitman et al. 2008), productivity (Connolly et al. 2001, Menge et al. 2004), species interactions (Menge et al. 2004), and intertidal biota (Blanchette et al. 2008). Many of these studies have highlighted Point Conception (Santa Barbara County, California) as a major feature of this coast that delineates a boundary between warm and cool water masses (Hickey 1979, 1993, Cudaback et al. 2005), biogeographic regions (Blanchette et al. 2008), and upwelling regimes (Menge et al. 2004). In addition to these abiotic characteristics, Broitman et al. (2008) observed coast-wide variation in recruitment dynamics in the mussel zone for intertidal mussels and 2 species of barnacles, finding low levels from northern California to Point Conception, with higher levels of *Balanus* recruitment and low levels of *Mytilus* recruitment south of Point Conception. The other species of barnacle, *Chthamalus*, showed more variability, with the highest recruitment rates observed in the Santa Barbara Channel (south of Point Conception) and variable but generally lower recruitment north of Point Conception (Broitman et al. 2008).

A broad-scale investigation of recovery of much bigger experimental clearings in the mussel *Mytilus californianus* and the turf alga *Endocladia muricata* assemblages has also been conducted along the California coast by Kinnetic Laboratories (1992) and Fos-

ter et al. (2003). While the geographic range of this study was set north of the present study and did not span Point Conception, there is spatial overlap with the present study at 2 sites: Pt. Sierra Nevada (see Fig. 1) and Diablo Canyon, a site approximately 60 km north of one of the current study sites (Stairs, see Fig. 1) (Kinnetic Laboratories 1992, Foster et al. 2003). The mussel component of these studies revealed slow recovery rates at all sites, with no significant relationship with latitude or season of clearing, and found slightly higher recovery rates at Diablo Canyon than at Pt. Sierra Nevada (Kinnetic Laboratories 1992). The *Endocladia* component of the study found different geographic patterns in recovery rate that depended on the season in which the disturbances were made, with the highest rates observed in spring-cleared plots at a site north of San Francisco and the lowest recovery rates observed at Diablo Canyon in fall-cleared plots (Foster et al. 2003).

#### Background: intertidal assemblages

The rocky intertidal is an ideal place to conduct a broad-scale investigation of resilience since ecologically relevant experimental disturbances can be made on spatial scales on the order of meters rather than kilometers and can be observed over the course of a few years rather than 100s of years, as would need to be the case for many other ecosystems. Because of the characteristic immersion gradient in rocky intertidal habitats, different species dominate at different tide heights (Menge & Branch 2001), permitting the exploration of recovery dynamics across zones consisting of species that display variation in life history characteristics (e.g. lifespan and dispersal capability) over spatial scales that are experimentally tractable.

I chose 4 intertidal zones characterized by different taxa that are common components of the rocky ecosystem across the west coast of North America (Blanchette et al. 2008) and because the dominant taxa in each assemblage exhibit variation in life history characteristics, such as lifespan and dispersal capability, that could lead to fundamentally different recovery dynamics. These taxa are: (1) the acorn barnacle *Chthamalus dalli/fissus* (hereafter, *Chthamalus*), a short-lived (1 to 3 yr) filter-feeder that has pelagic larvae, occurs as a distinct band in the high intertidal, and may disperse 10s to 100s of kilometers (Newman & Abbott 1980, Shanks et al. 2003); (2) the filter-feeding mussel *Mytilus californianus* (hereafter, *Mytilus*), which is longer-lived (7 to 20 yr),

occurs in the low-mid intertidal and also has pelagic larvae with dispersal potential similar to *Chthamalus* (Haderlie & Abbott 1980, Suchanek 1981); (3) the rockweed *Silvetia compressa* (hereafter, *Silvetia*), an alga which disperses centimeters to meters, occurs in the mid intertidal and can live for up to 7 yr (Gunnill 1980, Brawley & Johnson 1991, Hays 2006); and (4) the red turf alga *Endocladia muricata* (hereafter, *Endocladia*), which typically occurs in the high-mid intertidal and is not well-studied with respect to either dispersal capability or lifespan but, as a red alga, likely has a shorter dispersal capability than *Chthamalus* or *Mytilus* and a shorter lifespan than *Silvetia*.

I predicted that I would observe faster recovery of the shorter-lived taxa (*Chthamalus* and *Endocladia*) and that recovery rates of *Mytilus* and *Chthamalus* would be reflective of previously observed geographic patterns in recruitment (Broitman et al. 2008) and growth (Blanchette et al. 2007), with highest recovery rates south of Point Conception.

## MATERIALS AND METHODS

### Study location

To determine the extent of geographic variation in recovery dynamics along the west coast of the United States, I selected 3 rocky intertidal sites along the California coast that spanned 2 biogeographic regions: Point Sierra Nevada (north of Point Conception), Stairs (near Point Conception), and Point Fermin (south of Point Conception) (Fig. 1).

### Experimental disturbances and censuses

I took a regression approach in understanding the effects of disturbance size on recovery rates and trajectories. As such I selected a gradient of disturbance sizes to implement experimentally. This permits a more precise understanding of the relationship between disturbance size and recovery dynamics and allows using disturbance magnitude as a meaningful continuous covariate in statistical analyses. For logistical and ethical reasons, individual disturbance sizes in the gradient were not replicated within sites and assemblages. While this lack of replication places limitations on the type of statistical test that may be used to compare dynamics across the treatments, it is nonetheless appropriate for a regression design.

In Fall of 2003, I established 8 recovery plots of the following sizes: 8 × 12 cm, 10 × 15 cm, 13 × 20 cm, 16 × 24 cm, 22 × 33 cm, 30 × 45 cm, 40 × 60 cm, and 50 × 75 cm in the *Chthamalus*, *Mytilus*, *Endocladia*, and *Silvetia* communities at each of the 3 study locations. These clearings were chosen to represent a suite of disturbance sizes that fell within the natural range for this system (e.g. Sousa 1984). The size of disturbance could potentially be caused by wave dislodgement, sand scour, or tar smothering. In each intertidal zone, plots were haphazardly located within the tidal elevation dominated by the target species (*Chthamalus*, *Mytilus*, *Endocladia*, or *Silvetia*), avoiding vertical walls, large crevices, and tidepools. I also established three 50 × 75 cm control (undisturbed) plots interspersed among the disturbed plots in each assemblage. In the disturbed (recovery) plots, I cleared the substratum of all visible biota and then burned each plot with a hand-held propane torch to remove microscopic propagules (sensu Lubchenco & Menge 1978, Murray & Littler 1978, Sousa 1979, Foster et al. 2003). All experimental clearings were made within a matrix of intact biota. Sampling consisted of placing 2.54 cm diameter (¼") PVC rectangular frames (for larger plots) or thin stainless steel rectangular tubes (for smaller plots) of the appropriate size strung with a uniform grid of monofilament line and noting the identity and location in the grid of species occupying the primary substratum and canopy (if present) under each intersection; thus for a given point, multiple species could be recorded. If it lay within the experimental plot, canopy-forming algae from sur-

Fig. 1. Study locations north of (Point Sierra Nevada), near to (Stairs), and south of (Point Fermin) Point Conception in California, USA

rounding undisturbed plots were counted as being part of the plot. Due to the range of plot sizes, plots differed in the number of points used to sample them, such that the largest 5 plots were sampled with 100 evenly spaced points, and the 3 smallest plots were sampled with 50, 40, and 30 points, respectively. All plots were marked with stainless steel screws in the corners to ensure consistency in the placement of the quadrat on each sampling visit. Plots were sampled prior to clearing and reassessed every 4 to 6 mo until spring of 2008, a span of 52 mo, encompassing 11 censuses.

### **Measuring recovery rates in the *Mytilus*, *Chthamalus* and *Endocladia* assemblages**

Recovery was determined by quantitatively comparing each disturbed plot to undisturbed control plots by calculating the Bray-Curtis similarity index (Bray & Curtis 1957) between every cleared plot and each of the 3 control plots within that intertidal assemblage, resulting in 3 estimates of community similarity for each recovery plot at each time interval. I also calculated the similarity of the controls to one another (sensu Murray & Littler 1978, Kinnetic Laboratories 1992, Foster et al. 2003) to establish a recovery 'threshold' that was defined as the point in time at which the mean similarity of a disturbance plot became greater than or equal to the mean similarity of the controls to one another ( $n = 3$ ) minus 1 standard deviation. In this way, natural variability at each site in each intertidal assemblage helped to define the recovery threshold. Once a plot passed the threshold, it was considered recovered regardless of later fluctuations. To estimate recovery rate for every disturbance plot, I calculated the slope of the line passing through 2 points i.e. the point at which the plot was disturbed and the point in time at which it recovered such that for a given plot,  $x$ -values were months since disturbance and  $y$ -values were Bray-Curtis similarity to each control plot. For plots that had not met the recovery threshold, rate of recovery was calculated using the 52 mo of available data.

### **Measuring recovery rate in the *Silvetia* assemblage**

In the *Silvetia* assemblage, a different metric for measuring recovery rate was used due to the high percent of algal canopy and bare rock in both recovery and control plots as well as the spatial and temporal variability of canopy cover. Here I simply used the

cover of *Silvetia* in the control plots as the metric for recovery, calculating the mean percent cover (across the 3 control plots) minus 1 standard deviation to define the threshold for recovery compared to the percent cover of *Silvetia* in each recovery plot. As with the other assemblages, I estimated recovery rate by calculating the linear slope using only the time interval immediately after clearing and the interval at which the percent cover reached threshold level. Since *Silvetia* exhibited greater seasonal fluctuations compared with other assemblages, each plot had to remain in this recovery envelope over at least 2 consecutive seasons (e.g. both fall and spring samplings) to be considered recovered.

### **Comparing recovery rates**

To assess differences in resilience across assemblages, I compared the distributions of the observed times to recovery. The maximum possible observed recovery time was 52 mo (the end of the study). To determine the effects of plot size and geographic location (site), I conducted an analysis of covariance (ANCOVA) (Systat v.12) within each assemblage with recovery rate as the dependent variable, geographic location as the main predictor variable, and disturbance size (the natural log of the plot area) as the covariate. This analysis was chosen over a nested ANOVA because it permits the explicit inclusion of a continuous covariate (disturbance size). When there was a non-significant interaction term, I removed this term and applied the reduced model. I applied Tukey's post-hoc test to compare pairs of sites when appropriate. To further examine the relationship between disturbance size and recovery rate within sites, I conducted linear regressions (Systat v.12) using recovery rate as the dependent variable and disturbance size as the predictor variable.

### **Treatment of outliers and natural catastrophes**

There were 2 plots with recovery rates that were drastically different from the other plots, and inclusion of these plots in the analyses masked underlying patterns among sites and among disturbance sizes. These plots both had *a priori* reasons related to their placement that could have led to the anomalous results. The *Endocladia* plot at Stairs was located in a more offshore and somewhat lower tidal elevation than the other plots, which could have led to its being more subject to sand and wave scour than appeared

to be typical for the rest of the assemblage, thus resulting in its slower observed recovery rate. The mussel plot at Stairs was located in a depression in the substratum such that the vertical thickness of the mussel bed surrounding this plot was greater than the rest of the plots and, as such, likely contributed to its much faster recovery by near-immediate collapse of the adjacent mussel bed into the clearing. These plots were included in Fig. 6 (labeled with asterisks) but are treated as outliers and omitted from all statistical analyses, averaged figures, and regression lines. At the conclusion of the study (spring of 2008), 2 of the *Endocladia* plots at Stairs were obliterated by breaking rock. These plots had already recovered so this occurrence did not affect the analysis of recovery rates but since the analysis of trajectories included all sample intervals (described below), I left this interval out of the comparison of trajectories for the *Endocladia* assemblage so as not to violate the statistical analysis, which requires no missing data.

#### Measuring community recovery trajectories within assemblages

Analysis of recovery trajectories permits explicitly comparing the timing and nature of ecologically relevant shifts in community composition across disturbance sizes and geographic locations. To compare community recovery trajectories, for each sample interval I used a method that is analogous to a 2nd stage MDS (PRIMER v.6). This technique is described in Clarke et al. (2006) whereby community change over time in a given plot can be first represented using a similarity matrix (1st stage MDS) followed by an explicit comparison of multiple similarity matrices representing different plots (2nd stage MDS), permitting visual inspection of recovery trajectories in MDS space and comparing them statistically using ANOSIM (PRIMER, v.6). However, this powerful technique has 2 drawbacks: (1) it does not readily integrate undisturbed or reference plots into graphical depictions of recovery trajectories, and (2) It is not possible to conduct a 2nd stage analogue to SIMPER (PRIMER v.6) whereby important time intervals and taxa may be identified as driving observed differences between trajectories.

To compare community recovery trajectories in a way that both incorporates the relationship between experimental and reference plots and that also permits the determination of the causes of observed differences in recovery trajectories, I first calculated

the difference between species-specific cover in each disturbed plot and the mean cover for each species in the control plots, thus integrating the relationship between recovery and control plots into the analysis. I then used non-normalized principal component analysis (PCA) to reduce these differences in species composition at each timestep to a single non-normalized PCA axis or factor (PC1), calculating the coefficients for each species in the community (PRIMER v.6), similar to the approach taken by O'Leary & McClanahan (2010) who used principle component factors for a multiple regression analysis and then related coefficients to particular taxa. Loadings for each species were calculated by finding the Pearson correlation between the composite variable (PC1) and the original data (Systat v.12). I compared trajectories by calculating Euclidean distances of this single principal component between all pairs of recovery plots within a species assemblage over time and across locations. I then used MDS on the Euclidean distances to compare trajectories across disturbance sizes and across locations (PRIMER v.6). To assess community changes over time in the undisturbed (control) plots, I randomly chose 2 of the 3 control plots and calculated the principal component score on the difference between them, generating one control value for every timestep at each site. I included these control trajectories in graphical depictions of recovery (MDS plots, PRIMER v.6) but did not include them in statistical comparisons of recovery trajectories. I conducted 1-way ANOSIM tests (PRIMER v.6) to assess whether recovery trajectories differed across geographic locations and another set of 1-way ANOSIM tests to assess whether trajectories differed with respect to disturbance size.

To determine which time intervals and which taxa drove observed differences in trajectories, I conducted SIMPER analyses (PRIMER v.6), allowing me to determine the important time intervals driving differences in recovery trajectories, as well as the taxa contributing to these differences, through examination of the PC1 coefficients. In this way it was possible to identify not only when trajectories differed but also which taxa were likely responsible for the observed differences. However, since plots were sampled every 4 to 6 mo, it is possible that differences in timing of important recovery events across sites or disturbances were treated as a single event and thus obscured. For this reason, the analysis is conservative such that only events that occur at timescales greater than the sampling frequency are detected.

## RESULTS

### Recovery rates

Although there was considerable variation in the amount of time to recovery, the median recovery times for *Chthamalus* and *Endocladia* communities were 15 and 25 mo, respectively, while those observed in the *Mytilus* and *Silvetia* communities were much longer, having median recovery times of 40 and 35 mo, respectively. Indeed, in both the *Mytilus* and *Silvetia* assemblages, 25% of the plots displayed recovery times that were greater than or equal to the length of the study (52 mo) (Fig. 2). Despite this, unrecovered plots generally exhibited temporal trends toward convergence with control plots (Figs. 3 & 4). Both invertebrate assemblages (*Chthamalus* and *Mytilus*) showed the slowest recovery at Stairs (near Point Conception) (Table 1; Fig. 5), and the highest recovery rates for *Chthamalus* were observed south of Point Conception. By contrast, the algal assemblages showed more variability with respect to across-site variation in recovery rates such that recovery rates across sites were statistically similar for both the *Endocladia* and *Silvetia* assemblages, although there was a clear trend towards slower recovery at the northern site (Point Sierra Nevada) in the *Silvetia* assemblage (Table 1; Fig. 5).

The effect of disturbance size on recovery rate was most consistent across the 3 study locations in the *Mytilus* assemblage, where recovery rates slowed with increasing plot sizes at all 3 sites (Fig. 6). In the *Chthamalus* assemblage, the negative relationship between disturbance size and recovery rate was sig-

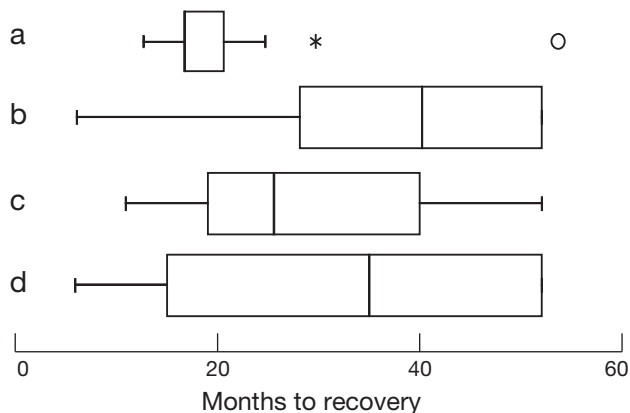

Fig. 2. Distribution of observed recovery times for all plots in the (a) *Chthamalus*, (b) *Mytilus*, (c) *Endocladia*, and (d) *Silvetia* assemblages at each of the 3 study locations over the course of the 52 mo study. The asterisk indicates values >1.5 times the interquartile range, and the open circle indicates values >3 times the interquartile range

nificant only at Stairs, and there was no relationship at any site for the *Silvetia* assemblage (Fig. 6). By contrast, *Endocladia* showed a positive relationship between clearing size and recovery at Stairs and a trend towards a negative relationship at Point Sierra Nevada (Fig. 6), resulting in a significant site by disturbance area interaction (Table 1).

### Recovery trajectories

The PC1 axis in the *Chthamalus* assemblage explained 98% of the variation and so provided a highly robust metric for examining recovery trajectories over time. The community components with the highest loadings were bare rock and *Chthamalus*. Bare rock showed a strongly negative coefficient while both live and dead *Chthamalus* showed positive coefficients (Table 2), signifying that a disturbed plot would transition from negative PC1 scores (more rock relative to controls) to positive ones (more *Chthamalus*) over time. An MDS plot comparing trajectories revealed that *Chthamalus* community recovery trajectories at Stairs and Point Fermin were the most different and that all 3 sites had recovery trajectories that were distinct from one another (Fig. 7). An ANOSIM test showed that there was a significant site effect ( $R = 0.49$ ;  $p = 0.001$ ) and no effect of plot size ( $R = -0.183$ ;  $p = 0.986$ ), suggesting that site-specific differences in recovery trajectories were more important than the dynamics of individual plots of varying size.

Analysis of the timing of community shifts in recovery showed different patterns across the 3 study sites. No timesteps stood out as contributing to the majority of the variation between observed recovery trajectories at Point Sierra Nevada and Stairs (Table 3). By contrast, the 3 intervals driving the observed differences between recovery trajectories observed at Point Sierra Nevada and Point Fermin were all in the year 2005 (Table 3). At these timesteps, Point Fermin had more positive PC1 values, indicating that there were major shifts toward communities consisting of *Chthamalus* and less bare rock relative to control plots than at Point Sierra Nevada. Similarly, 3 time intervals drove nearly 40% of the variation in observed differences in community recovery trajectories between Stairs and Point Fermin in the *Chthamalus* assemblage (Table 3) however these intervals were both early (0 and 3 mo) and later in the successional process (19 mo). The differences appeared to be driven by increased rock in the recovery plots relative to the controls (a more negative average PC1

value) at Point Fermin at the 0 and 3 mo intervals followed by a shift to more *Chthamalus* in the recovery plots at Point Fermin than at Stairs at the 19 mo time interval (Table 3).

In the *Mytilus* assemblage, the PC1 axis described 75% of the variation in community composition. The species with the highest loadings and positive coefficients were *Mytilus californianus* and the gooseneck barnacle *Pollicipes polymerus*, while bare rock had highly negative coefficients (Table 2), indicating that a recovering plot would transition from more negative scores (more rock relative to the controls) towards more positive ones (a community comprised mainly of *Mytilus* and *Pollicipes*). *Mytilus* community recovery trajectories differed significantly across geographic locations ( $R = 0.24$ ,  $p = 0.003$ ) but not by disturbance size ( $R = 0.07$ ,  $p = 0.238$ ) (Fig. 7). SIMPER analysis showed that between Point Sierra Nevada and Stairs, the greatest differences were later in succession (Table 3), with these differences contributing to nearly half of the observed variation. PC1 values were higher (more positive) at Point Sierra than Stairs at all 3 intervals, indicating a shift in community composition towards recovery (higher cover of *Mytilus* and *Pollicipes*) at Point Sierra Nevada but not at Stairs at these timesteps. By contrast, the interval driving the majority of variation in recovery trajectories between Point Sierra Nevada and Point Fermin was somewhat earlier in succession, such that Fall of 2005 (23 mo)

Fig. 5. Average recovery rates (across disturbance sizes) across sites within the *Chthamalus*, *Mytilus*, *Endocladia*, and *Silvetia* assemblages. Different letters indicate significant ( $p < 0.05$ ) differences. Data are shown as mean ( $\pm$ SEM)

Fig. 6. Linear regressions between recovery rate and disturbance size within each assemblage at each location for the (a–c) *Chthamalus*, (d–f) *Mytilus*, (g–i) *Endocladia*, and (j–l) *Silvetia* assemblages. Asterisks indicate outliers that were not used in the calculation of the regression statistics or line

Table 2. Coefficients and loadings for each species from the principal components analysis (non-normalized). Data shown for species with loadings with an absolute value above 0.25

| Assemblage Species                            | Latent eigenvector (coefficient) | Loading (absolute value) |
|---|----------------------------------|--------------------------|
| <b>Chthamalus</b>                             |                                  |                          |

contributed the most variation (Table 3). In this case, the PC1 score of Point Sierra Nevada was more negative relative to the highly positive value at Point Fermin, indicating that at this time interval, there were more early successional community components at Point Sierra Nevada and more late successional components at Point Fermin relative to the control plots (Table 3). The time intervals driving differences be-

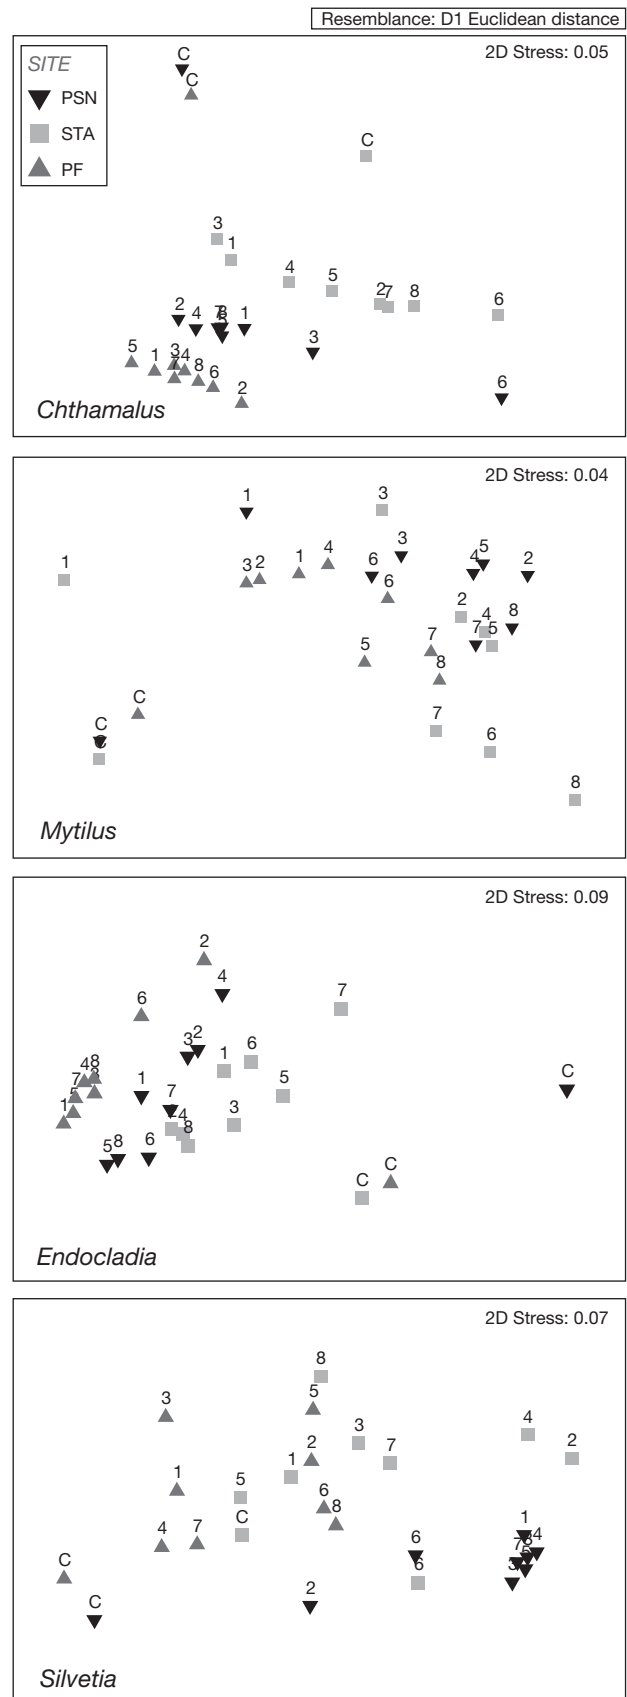

Fig. 7. MDS plots of recovery trajectories in the *Chthamalus*, *Mytilus*, *Endocladia* and *Silvetia* assemblages. Each point represents the trajectory (change in PC1 score of the difference in species composition between control and recovery plots) over time for a given plot where numbers correspond to plot sizes such that 1 = smallest and 8 = largest. The trajectories of the difference between 2 random control plots for each assemblage at each site are depicted by the letter C. See Fig. 3 for site abbreviations

Table 3. Results of SIMPER analyses identifying the time intervals most responsible for driving observed differences between recovery trajectories across geographic locations. The intervals with the 3 highest percentage contributions to differences are presented for each pair of sites within each assemblage. The average PC1 scores at each site at the important intervals are also reported. (PSN, Point Sierra Nevada; STA, Stairs; PF, Point Fermin). Intervals are indicated by season (FA: fall; WI: winter; SP: spring; SU: summer) and year of disturbance, with months since disturbance (0 to 52) in parentheses

| Assemblage Comparison | Interval (months) | Avg. PC1 |       |        | Percentage |

tween Stairs and Point Fermin all occurred later in succession, with 23, 28, and 52 mo all contributing to over 40% of the variation in trajectories. At all 3 of these timesteps, recovery plots at Point Fermin consisted of more late successional species (more positive scores) than Stairs relative to the controls (Table 3). Thus, as with the *Chthamalus* assemblage, both recovery rates and trajectories displayed significant geographic variation in the *Mytilus* assemblage.

In the *Endocladia* assemblage, the PC1 axis explained 54.4% of the variation in community recovery trajectories. The components with the highest loadings and positive coefficients were bare rock and *Mytilus californianus*, whereas the species with the most negative coefficients were *Endocladia*, the red alga *Mastocarpus* spp, crustose brown algae, and the green alga *Cladophora columbiana* (Table 2). In this assemblage, the component scores of a recovering community transitioned from positive (rock-dominated) to more negative (communities dominated by *Endocladia* and *Mastocarpus*) over time. The MDS plot showed that all 3 sites had distinct recovery trajectories and that recovery trajectories differed by site ( $R = 0.541$ ;  $p = 0.001$ ) and not by plot size ( $R = -0.266$ ;  $p = 0.999$ ) (Fig. 7). As with the *Chthamalus* assemblage, the intervals driving differences between Point Sierra Nevada and Stairs in the *Endocladia* assemblage all occurred in the year 2005, and these intervals explained over 50% of the variation in trajectories (Table 3). In each case, PC1 scores were much more negative at Stairs, indicating a stronger shift towards recovery relative to Point Sierra Nevada, which had more positive scores at these intervals indicating more bare rock and earlier successional species. The most important 2 intervals driving differences between Point Sierra Nevada and Point Fermin were later in succession (48 and 40 mo, respectively) (Table 3) which together explained nearly 40% of the variation. At these timesteps, Point Sierra Nevada had more negative PC1 scores, indicating a more

fully-recovered community than Point Fermin. The 2 most important time intervals driving the differences in recovery trajectories between Stairs and Point Fermin were 11 and 15 mo, which contributed to over 40% of the variation and where Stairs had more negative PC1 values indicating that the communities there were more intact (Table 3)

In the *Silvetia* assemblage, the PC1 axis explained 45.5% of the community variation in recovery trajec-

tories in the *Silvetia* assemblage. *Silvetia*, *Mytilus*, and *Cladophora* had the highest loadings and positive coefficients while bare rock was strongly negative (Table 2), indicating that a recovering plot would be expected to transition from more negative PC1 values to more positive ones over time. The recovery trajectories at Point Sierra Nevada were visually distinct from those at Stairs and Point Fermin, showing a significant effect of site ( $R = 0.49$ ;  $p = 0.001$ ) but not disturbance size ( $R = 0.236$ ;  $p = 0.995$ ) (Fig. 7). The most important intervals driving differences between Point Sierra Nevada and Stairs were later in succession (35 and 48 mo), and together, these intervals accounted for nearly 40% of the variation in trajectories (Table 3).

## DISCUSSION

The capacity of communities to recover from disturbances is a key component of the functioning of natural ecosystems and is becoming an important aspect of effective management (Hughes et al. 2005). The dramatic variation I observed in recovery rates and trajectories shows that resilience is both an inherently spatial and species-specific quality, such that differences in recovery rates are best understood in both in the context of life history characteristics of the disturbed taxa and of biogeographic region where the disturbance has occurred. The result that the barnacle assemblage showed the fastest overall recovery is not surprising given its relatively short lifespan and that it is well understood that barnacles typically settle onto bare rock (e.g., Raimondi 1988), which is the most available substratum after a clearing disturbance in this system. This rapidity of recovery in barnacle-dominated communities has also been observed by Viejo (2009). Barnacles produce larvae that can disperse on the order of 10s to 100s of kilometers (Newman & Abbott 1980, Shanks et al. 2003), increasing the likelihood of the arrival of new propagules to a given location. Of the dominant intertidal species in this study, *Chthamalus* is the shortest-lived; it can reach reproductive maturity on the order of months (Hines 1978), and is, thus capable of producing new recruits relatively quickly after a disturbance. This increased window of reproductive activity likely results in a much higher availability of propagules compared to the other species in this study. On geographic scales, this attribute likely contributes to the overall availability of propagules at a given time or location (Chapman & Underwood 1998). The life history characteristics of *Endocladia*

also favor shorter population turnover times and likely affected overall recovery rates for this assemblage. *Endocladia* is capable of recruiting into clearances through expansion via vegetative growth as well as through either the settlement of haploid or diploid spores originating from adult thalli. These multiple mechanisms of new space occupation by the dominant taxon could contribute to the relatively rapid recovery of the *Endocladia* assemblage. The timing of recovery found in this study (from 11 to >52 mo) in the *Endocladia* assemblage is consistent with the findings of Foster et al. (2003) who observed that larger ( $1 \times 2$  m) disturbances varied in recovery times from 1 to >6 yr. However, while I observed little among-site variation in the *Endocladia* assemblage recovery rates, Foster et al. (2003) found more geographic variation and generally slower recovery at their southernmost site, Diablo Canyon, than Point Sierra Nevada. Foster et al. (2003) found similar rates of recovery between fall- and spring-cleared plots in 3 of the 6 sites, faster recovery of spring-cleared plots at 2 of the sites (including Diablo Canyon), and faster recovery in fall-cleared plots at Point Sierra Nevada. The current study is analogous to fall-cleared plots; however because of the variable effect of season in Foster et al. (2003), it is difficult to determine how the season of clearing may have affected variation in recovery rates across sites in the current study.

The *Mytilus* assemblage had highly variable recovery rates that were directly related to disturbance size at all locations. It is well documented that adult mussels have the capacity to encroach into gaps in mussel beds (e.g. Paine & Levin 1981) so smaller plots will experience this to a higher degree due to their higher perimeter to area ratio. The larger the disturbance in a mussel bed, the greater the reliance will be on recovery by larval input (Connell & Slatyer 1977). Mussels, like barnacles, have propagules that are long-dispersing, but, unlike barnacles, they have specific habitat requirements for settlement such that they do not typically settle on bare rock but instead attach to the byssal threads of adult conspecifics or in some cases, turf algae (Menge et al. 1994). This means that for mussel recovery by recruitment, there must be both available larval propagules and suitable settlement sites as well as facilitation by conspecifics or others. Since these requirements may not align spatially or temporally (i.e. there might be available propagules but no available settlement sites or vice versa) and since mussels are more slow-growing than barnacles, the slower recovery of mussels relative to barnacles is consistent with their life history strategy. Recovery via encroachment vs. re-

recruitment was not directly quantified in this study, but encroachment was inferred to some degree in all experimentally disturbed plots at all sites (by the increasing presence of adult mussels at the perimeter of experimental disturbances).

The *Silvetia* assemblage displayed the most variable, as well as the slowest, recovery rates observed in this study (Figs. 2 & 6). Since the smallest recovery plots typically had a greater proportion of the plot covered by canopy from surrounding undisturbed individuals, small disturbances in this assemblage recovered very quickly, contributing to the overall variability in recovery rates in this assemblage. Larger disturbances were more likely to be reliant on successful propagule establishment for recovery. *Silvetia* releases thousands of gametes that have very high fertilization success but very low recruitment and subsequent colonization rates (Brawley & Johnson 1991). *Silvetia* lives for several years (Gunnill 1980) so relatively few successful recruitment events are required for population persistence. *Silvetia* propagules (zygotes) disperse on the order of centimeters to a few meters (Brawley & Johnson 1991). This means that the recovery from disturbances through successful recruitment events will be dependent on local fecundity and post-settlement survival, both of which may show considerable seasonal and geographic variability. In particular, benign microhabitats such as facilitator species (Brawley & Johnson 1991) or topographic heterogeneity (Lubchenco 1983) have been shown to be important in increasing the likelihood of juvenile fucoid survival. Geographic or local variation in the availability of such microhabitats as well as in the importance of grazers (Coleman et al. 2006) are likely contributors to the extreme variation in recovery rates that I recorded for this assemblage and to the very slow recovery rates observed at Point Sierra Nevada. Previous studies of fucoid recovery have also showed variation and maximum recovery times on the order of years (e.g. Farrell 1991).

Both invertebrate-dominated assemblages (*Mytilus* and *Chthamalus*) showed spatial variation in recovery rates, with the slowest rates observed at Stairs, the site closest to Point Conception. This general pattern was observed by Raimondi et al. (1999) for zone-specific *Mytilus* and *Chthamalus* recruitment, and an investigation by Broitman et al. (2008) of mussel and barnacle recruitment in the mussel zone also showed a marked increase in *Chthamalus* recruitment south of Point Conception, while finding similar levels of *Mytilus* recruitment both north and south of the point. This suggests that geographically

varying recruitment and/or larval supply, particularly for *Chthamalus*, are possible mechanisms driving the observed pattern of fastest recovery of *Chthamalus* south of Point Conception (Fig. 5), although this may not explain differences between the northern 2 sites. Higher growth rates of mussels in the warmer water south of Point Conception (Blanchette et al. 2007) as well as spatial variability in rates of predation (Menge et al. 2004) likely contribute to the geographic variability observed in recovery rates and trajectories of mussels, such that higher growth rates south of Point Conception may have compensated for similar rates of input. The contrasting rates of mussel recovery observed in this study between Point Sierra Nevada and Stairs differ from recovery observations made by Kinnetic Laboratories (1992) who found the opposite pattern in recovery rates for bigger (1 × 2 m) clearings between Pt. Sierra Nevada and Diablo Canyon, a site north of Stairs, suggesting that the geographic patterns observed in this study may not be representative of each region as a whole.

I also found variable effects of disturbance size across study locations that differed with intertidal assemblage (Fig. 6). The manner in which sites vary in their response to different sizes of disturbance is suggestive of potentially different mechanisms at play across sites. For example, in the *Chthamalus* assemblage, the site with the slowest recovery rate (Stairs) was also the only site to show a pattern with respect to disturbance size. In this assemblage, gregariousness with conspecific adults (positive edge effects) appeared to be driving the increased recovery rates in smaller plot sizes. Thus, where recovery is faster, such edge effects may be less important, suggesting that the strength of interspecific interactions varies across locations, a phenomenon that has been documented in intertidal systems for trophic interactions, such as predation (Menge et al. 2004) and herbivory (Coleman et al. 2006). Alternatively, edge effects may be similar at the 3 sites, but where recovery occurs faster, such effects may have required more frequent observations to be measured effectively.

Strikingly, in the *Endocladia* assemblage, the edge had a trend towards positive effects at 2 sites (Point Sierra Nevada and Point Fermin) but had a significant negative effect at Stairs. This result is consistent with the findings of Sousa (1984) who found greater abundances of *Endocladia* in larger experimental patches than in smaller ones, indicating that the center of large disturbances at this site could be a refuge from herbivores or other negative edge effects such

as shading. It also challenges the notion that the relationship between recovery rate and disturbance size is static for a given species or location and underscores the importance of conducting studies across broad spatial scales.

The timing of key events driving differences in community recovery trajectory (Fig. 7) differed across sites and assemblages (Table 3). In some cases, such as between the *Chthamalus* plots at Point Sierra Nevada and Point Fermin, the important intervals identified were relatively close to one another in time, suggesting a major series of ecologically relevant occurrences (i.e. recruitment, predation, or growth events) as being important in the divergences between pairs of sites (Table 3). In this case, since Point Fermin showed positive principal component scores relative to Point Sierra Nevada at all 3 intervals (Table 3), an increase in *Chthamalus* cover driven by recruitment or growth was likely responsible. By contrast, other comparisons identified intervals, both early and in late succession, that drove differences in recovery trajectories (e.g. *Endocladia* plots at Stairs and Point Fermin) and suggested events that led to higher cover of *Endocladia* and *Mastocarpus* at Stairs (more negative PC values) than at Point Fermin (Table 3) throughout succession. The extent to which recovery rates and trajectories mirror one another can also provide important insights into the recovery process. I found that successional trajectories were different across geographic locations within all 4 intertidal assemblages and appeared to be driven by differences in the timing of community shifts from bare rock and early-mid successional species to a greater abundance of the dominant species in each assemblage (Tables 2 & 3). I found these differences even in the 2 algal-dominated intertidal assemblages where community recovery rates were statistically similar, suggesting that similar recovery rates may be driven by very different ecological processes. Since, like most species of algae, both *Endocladia* and *Silvetia* have propagules that disperse at more local scales (meters rather than kilometers), the timing and availability of viable recruits is likely to be reliant to some degree on local fecundity, which can differ seasonally and geographically (Foster et al. 2003) and thus contribute to observed differences in the timing of community shifts towards later successional taxa. Spatial and temporal variation in key processes, such as recruitment and consumer pressure, combined with site-specific differences in the relative importance of mechanisms driving recovery may also contribute to observed geographic variation in both recovery rates and trajectories.

## CONCLUSIONS

As both ecological insights (e.g. Gouhier et al. 2010) and resource management (Halpern et al. 2007) shift toward more spatially explicit approaches, understanding variation in the likely responses to natural and anthropogenic perturbations is becoming increasingly important. Here, I have demonstrated that, for disturbances that result in complete loss of biomass (e.g. rock breaking, pressure-washed oil spills), shorter-lived taxa are more likely to show faster recovery, and thus higher resilience, than those that are longer-lived, and that the 2 longer-dispersing taxa in this study showed similar geographic variation in recovery rates. Importantly, I show that while there exist some generalities across locations in recovery rates, recovery trajectories were distinct for each location, highlighting the need for elucidation of both site-specific mechanisms of recovery and the need to consider variation in recovery in management planning.

*Acknowledgements.* I am deeply grateful to P. Raimondi, D. Doak, S. Murray, I. Parker, and J. Pearse for their invaluable insights and editorial comments throughout this study. I am also grateful for the thoughtful and thorough comments of 3 anonymous reviewers. This work could not have been completed without the tireless assistance in the field from many people including M. Miner, C. Bell, H. Hayford, M. Bond, P. Raimondi, D. Lohse, L. Anderson, L. Reeve, H. Livingston, A. Kendall, M. Williams and M. Helix. For access to field sites and logistical help I thank J. Milgrim, K. Milgrim, D. Canestro, M. Canestro, the Hearst Ranch Corporation, Vandenberg Air Force Base, Rancho Marino University of California Reserve and the Cabrillo Aquarium. This paper benefited from discussions and comments from T. Klinger. Funding for this study was provided by the Mineral Management Service (MMS), the Partnership for Interdisciplinary Studies of Coastal Oceans (PISCO), a National Science Foundation dissertation improvement grant (DEB 0808012), Friends of Long Marine Lab, the Earl and Ethel Meyers Oceanographic Trust, and the Marilyn C. Davis Memorial Grant.
