ABSTRACT: Sexual segregation is common among marine mammals, leading to intraspecific differences in diet, diving behaviour, home range size and even latitudinal distribution and migratory patterns. Sperm whales *Physeter macrocephalus* present one of the most extreme examples of sexual dimorphism both in size and social structure, with males and females segregating at different latitudes across most of their range, but the underlying ecological drivers remain unclear. Studying fine-scale dietary and habitat differences where the sexes occur in sympatry could therefore provide insights into the mechanisms underpinning their large-scale segregation. In this study, we analysed the carbon and nitrogen stable isotope values in the skin of males and females from an isolated, endangered population inhabiting the Mediterranean Sea, sampled in a region where the sexes occur and feed regularly in the summer months but show subtle differences in habitat preference. We found marked differences in both carbon and nitrogen isotopic values between the sexes, indicating that they could be targeting prey items in different trophic levels and habitats. Combined with the evidence from habitat modelling studies, our results suggest that female and male sperm whales segregate even in the latitudinally restricted Mediterranean population, at a much smaller scale. This sympatric, fine-scale sexual segregation suggests that reduction of competition may have been a key factor in the evolution of the social structure and large-scale latitudinal segregation of this species.

1. INTRODUCTION

Sexual segregation is a widespread phenomenon in animal ecology (Ruckstuhl 2007, Main 2008), with important implications for both the theoretical understanding of population and ecosystem dynamics, and the design of effective conservation efforts (Wear-

mouth & Sims 2008). Among marine mammals, key top-down drivers of marine community structure (Bowen 1997, Williams et al. 2004, Baum & Worm 2009), social and habitat segregation can result in sex differences in diet, diving behaviour, home range size and even latitudinal distribution and migratory patterns (Wearmouth & Sims 2008). Such variation has

been described in many pinnipeds (e.g. Lesage et al. 2001, Breed et al. 2006, Tucker et al. 2007, Bailleul et al. 2010, Kernaléguen et al. 2016) and some cetaceans (e.g. Marcoux et al. 2012, Gavrilchuk et al. 2014), particularly in species that show a high degree of body size dimorphism. Reproductive status, energetic requirements and intersexual competition have been proposed as potential explanations for these differences (Wearmouth & Sims 2008), but the proximate or ultimate mechanisms driving the evolution of sexual segregation are still debated (Ruckstuhl 2007).

Sperm whales *Physeter macrocephalus* are highly sexually dimorphic, with males being substantially larger than females. These morphological differences are thought to be largely due to sexual selection (Cranford 1999, Whitehead 2003). In most studied populations, social structure and broad-scale habitat use is also strikingly different between the sexes: females and young form long-lasting social units at latitudes approximately $<40^{\circ}$ N/S, while males become increasingly solitary with age and simultaneously move to increasingly higher latitudes (Whitehead 2003). The species is characterised by a diet mainly composed of mesopelagic cephalopods (Kawakami 1980, Clarke et al. 1993, Santos et al. 1999, Roberts 2003, Foskolos et al. 2020).

Analyses of stomach contents from stranded individuals have suggested some differences in diet between the sexes, with males targeting larger and deeper prey items and consuming additional non-cephalopod prey at high latitudes (e.g. Clarke et al. 1993, Best 1999, Flinn et al. 2002, Evans & Hindell 2004, Teloni et al. 2008). In addition to the latitudinal separation when not breeding, males and females also appear to show subtly different habitat preferences in regions and periods where they co-occur (e.g. Best 1999, Gregr & Trites 2001, Pirodda et al. 2011, 2020). Females tend to have higher feeding success in these areas, leading to the hypothesis that they outcompete males for the highest quality habitat (Clarke et al. 1988, Best 1999, Whitehead 2003). Together with reproductive requirements (e.g. the need to care for young individuals), these dietary and habitat differences could thus provide insights into the mechanisms underlying the evolution of sperm whale social structure, size dimorphism and ecology.

Stable isotope analysis is a powerful tool to investigate variation in diet among individuals or groups of individuals (Post 2002), but is limited by a low taxonomic resolution (Nielsen et al. 2018). Using this technique on sperm whale skin samples, Ruiz-Cooley et al. (2004) detected dietary differences between males and females in the Gulf of California. How-

ever, given isotope turnover rates, the authors suggested that these differences could reflect the diet of adult males in high-latitude feeding grounds or any period of fasting during their migration to lower latitudes, i.e. their large-scale latitudinal segregation, rather than sympatric differences in the area where they co-occurred with social units and were sampled. Such suggestions are consistent with the ontogenetic changes found in other studies (Mendes et al. 2007b). Similarly, Borrell et al. (2013) found sexual differences in isotopic values in sperm whale dentine samples from the northeast Atlantic, which they attributed to large-scale segregation and population structuring. Therefore, it remains to be confirmed whether males and females vary in their diet when they co-occur at lower latitudes.

A small population of sperm whales inhabits the Mediterranean Sea and is classified as Endangered on the IUCN Red List (Notarbartolo di Sciara et al. 2012). Genetic and photo-identification studies have shown that the population is isolated from the northeast Atlantic (Drouot et al. 2004a, Engelhaupt et al. 2009, Carpinelli et al. 2014, Alexander et al. 2016). Relative to sperm whales in other oceans, males in this population are thought to be generally smaller (Drouot et al. 2004b, Frantzis et al. 2014), possibly implying smaller differences in energy requirements and diving capabilities compared to females. Analysis of stomach contents of stranded Mediterranean individuals suggested a diet dominated by cephalopods of the genera *Histioteuthis* and *Octopoteuthis* (Roberts 2003, Foskolos et al. 2020).

Within this enclosed basin, the potential for the large-scale latitudinal segregation between sexes observed in other oceans is much reduced due to geographical constraints. Information on movements within the Mediterranean is limited, but photo-identification studies in the western basin have demonstrated that individuals can move between the area of the Ligurian Sea and Gulf of Lions, the Strait of Gibraltar and the waters around the Balearic archipelago (Spain), covering distances up to ~1600 km (Drouot-Dulau & Gannier 2007, Carpinelli et al. 2014, Rendell et al. 2014). The Balearic archipelago is an area where both female groups and singleton males are regularly encountered during summer monitoring surveys (Pirodda et al. 2011, 2020, Rendell et al. 2014). Both sexes are observed consistently engaging in long dives while actively searching for prey (as suggested by their echolocation activity), indicating they are feeding in this area in the summer months. At least in this season, the sexes thus appear to be sympatric at the regional scale, but there is evidence of

varying habitat preferences on finer spatial scales of approximately 10 km (Pirotta et al. 2011, 2020, Jones et al. 2016). Specifically, groups are encountered in deeper, warmer waters characterised by lower sea level anomaly compared to singletons, suggesting that the sexes may be segregating at these smaller scales (Pirotta et al. 2020). Therefore, the analysis of stable isotopes in this area could help our understanding of fine-scale sexual segregation in the species.

While previous studies have measured stable isotope values in samples from Mediterranean sperm whales (Mazzariol et al. 2011, Praca et al. 2011, Pinzone et al. 2015), none has explicitly assessed isotopic differences between sexes. Here, we analysed the

stable isotope values in the skin of male and female sperm whales sampled around the Balearic Islands, with the aim of exploring intraspecific differences in diet in a season where the sexes are encountered within the same region. These differences could indicate the occurrence of sexual segregation in a low-latitude area where the sexes are broadly sympatric. Dietary differences between males and females could reflect a differential use of the water column or of portions of the distribution range. In turn, this would affect their exposure to the human activities that threaten the survival of the population (Rendell & Frantzis 2016), thus highlighting the potential need for sex-specific conservation strategies.

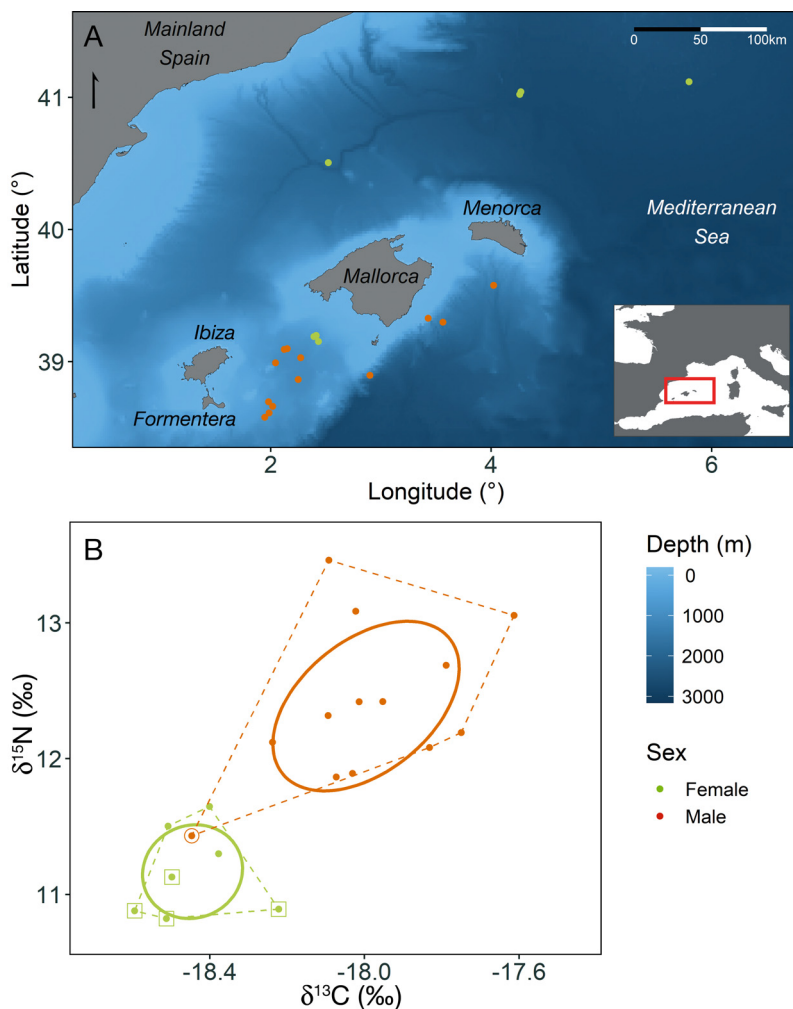

Fig. 1. (A) Locations of sperm whale biopsy sample collection and (B) $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$ values in skin samples, with solid lines representing standard ellipses corrected for sample size (SEA_C) and dashed lines representing convex hull areas. Sample comprises 7 females and 13 males. The observation corresponding to the small male with female-like isotope values is circled, while females sampled at latitudes $>40^\circ\text{N}$ are identified by squares

2. MATERIALS AND METHODS

2.1. Data collection

Between May and September 2019, sperm whales were approached to collect biopsy samples while at the surface between foraging dives using a 12 m auxiliary powered sailing yacht. We distinguished between encounters with single individuals and encounters with groups, defined as individuals (often including young animals) engaging in direct interaction or 'moving together in a coordinated fashion' (Whitehead 2003, p. 213).

Biopsies were collected using a 150 lb pull crossbow (Barnett International) and arrows with stainless steel sampling heads of 0.5 cm diameter and 2.5 cm length (Ceta-Dart). Arrows were shot from a distance of <15 m, aiming for the mid-lateral region of the body, below the dorsal fin.

We successfully collected biopsy samples from 20 individual sperm whales (Fig. 1A). Most individuals (90%) showed some short-term behavioural reaction to sampling, including startle, defecation, shallow diving, and horizontal avoidance. All sampled individuals were subsequently identified using photographs of their dorsal and caudal fin to avoid repeated sampling.

After retrieving the arrow, the sample was removed from the sampling head and divided in 2 parts longitudinally. One half was directly frozen onboard in an electric freezer (for stable isotope analysis), while the other half was placed in ethanol (for genetic sex

determination). The sampling heads were then sterilized using bleach and rinsed with 90% alcohol for subsequent reuse.

2.2. Laboratory analyses

All stable isotope analyses were undertaken at the Centres Científics i Tecnològics of the University of Barcelona. Subsamples of skin were defrosted, minced with scalpel and scissors and dried at 60°C for 48 h. Dried samples were treated with a chloroform-methanol (2:1) solution to extract lipids (Bligh & Dyer 1959). Lipid extraction can alter $\delta^{15}\text{N}$ values (Logan & Lutcavage 2008, Smith et al. 2020), but was required to prevent the confounding effect of lipids on isotopic values, in the absence of tissue- and species-specific lipid-normalization models (Lesage et al. 2010). Given that the aim of the study was to assess differences between the sexes, this technique was deemed appropriate, since the consequences of lipid extraction are primarily relevant when comparing isotopic values with putative prey or samples from other laboratories. Subsequently, samples were dried at 60°C for 48 h. The lipid content was determined as the difference in sample weight before and after the lipid-extraction treatment. Approximately 0.3 mg of each sample was weighed in tin capsules, automatically loaded and combusted at 1000°C for analysis in a continuous flow isotope ratio mass spectrometer (Flash 1112 IRMS Delta C Series EA Thermo Finnigan). Standards for $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$ were the Vienna Pee Dee Belemnite limestone (VPDB) and atmospheric nitrogen, respectively. International isotope secondary standards of known $^{13}\text{C}/^{12}\text{C}$ and $^{15}\text{N}/^{14}\text{N}$ ratios in relation to VPDB and atmospheric nitrogen, respectively, were used for calibration of $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$, namely: polyethylene (IAEA CH7; $\delta^{13}\text{C} = -31.8\text{‰}$), ammonium sulphate (IAEA N1; $\delta^{15}\text{N} = +0.4\text{‰}$ and IAEA N2; $\delta^{15}\text{N} = +20.3\text{‰}$), L-glutamic acid (USGS 40; $\delta^{13}\text{C} = -26.2\text{‰}$; $\delta^{15}\text{N} = -4.6\text{‰}$;) and caffeine (IAEA 600; $\delta^{15}\text{N} = 1.0\text{‰}$; $\delta^{13}\text{C} = -27.7\text{‰}$). The reference materials used are distributed by the International Atomic Energy Agency (IAEA) and were selected based on previous calibration experiments to ensure an optimum range of reference values. Calibration precision based on replicate measurements of the internal laboratory standards was $0.23 \pm 0.15\text{‰}$ for $\delta^{13}\text{C}$ and $0.19 \pm 0.11\text{‰}$ for $\delta^{15}\text{N}$. Results were expressed as per mil (‰) following the delta (δ) notation, according to the equation:

$$\delta^{13}\text{C} \text{ or } \delta^{15}\text{N} (\text{‰}) = \left[\left(\frac{R_{\text{sample}}}{R_{\text{standard}}} \right) - 1 \right] \cdot 10^3 \quad (1)$$

where R is the heavy-to-light isotope ratio ($^{15}\text{N}/^{14}\text{N}$ or $^{13}\text{C}/^{12}\text{C}$).

The determination of the sex of sampled individuals was conducted at the DNA/Molecular Genetics laboratory in the School of Biological, Earth and Environmental Sciences of University College Cork. Genomic DNA was extracted from each ethanol-preserved skin subsample using the Qiagen DNeasy® Blood and Tissue kit. Sex determination was carried out following Rosel (2003).

2.3. Statistical analysis

Differences in $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$ values between males and females were tested using Gaussian linear models; assumptions of residual normality and homogeneity of variance across sexes were assessed using Shapiro-Wilks and Levene's tests, respectively. Some individuals were sampled as part of the same group, which could imply that their dietary choices were not independent. Therefore, we also refitted the models using a working independence correlation structure in a generalised estimating equations (GEE) framework (Hardin & Hilbe 2003), where group identity was used as the blocking factor. A sandwich variance estimator provided robust estimates of precision accounting for the observed degree of autocorrelation within each block (Hardin & Hilbe 2003), which were used in a Wald's test to assess whether differences between the sexes were significant.

Frequentist standard ellipses (containing approximately 40% of the data) corrected for small sample sizes (SEA_C) were generated using package SIBER (Jackson et al. 2011) for R v3.6.0 (R Core Team 2019). The robust Bayesian framework implemented in SIBER was also used to estimate Bayesian standard ellipses (SEA_B) and compare isotopic niche widths for the 2 sexes. An uninformative inverse Wishart prior with 2 degrees of freedom and scale matrix $\begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}$ was used for the covariance matrix, while uninformative Gaussian priors with mean = 0 and precision = 0.001 were used for the means (package defaults). Markov chain Monte Carlo algorithms were run for 10^6 iterations (discarding the first 1000 iterations as burn-in).

3. RESULTS

Genetic sexing indicated that 7 sampled individuals were females, while the remaining 13 were

males. Among sampled males, 7 were recorded as singletons. Additionally, 3 males were sampled from a group of 7, even though they were not visibly smaller than other sampled males. The remaining 3 males were sampled while grouped together (without other individuals), and included a smaller, probably younger individual observed closely interacting with the boat and engaging in aerial displays. All sampled females were part of 4 separate groups.

Male $\delta^{15}\text{N}$ values ranged between 11.4 and 13.5‰ (mean \pm SD: $12.4 \pm 0.6\text{‰}$), while female $\delta^{15}\text{N}$ values ranged between 10.8 and 11.6‰ ($11.2 \pm 0.3\text{‰}$); $\delta^{13}\text{C}$ values ranged between -18.4 and -17.6‰ for males ($-18.0 \pm 0.2\text{‰}$), and between -18.6 and -18.2‰ for females ($-18.4 \pm 0.1\text{‰}$). The C:N ratio in the lipid-extracted skin samples fell between 3.1 and 3.6‰, confirming that the lipid extraction process was effective and did not affect $\delta^{13}\text{C}$ values (Ryan et al. 2012, Giménez et al. 2017).

SEA_C for males and females did not overlap (Fig. 1B). Using 10 000 posterior draws of SEA_B , a very small overlap was confirmed (mean = 3.6‰; median = 0‰). Stable isotope values for 1 sampled male differed markedly from other male $\delta^{15}\text{N}$ and $\delta^{13}\text{C}$ values, falling within the female convex hull; this was the smaller individual sampled in a group of 3. The Gaussian models highlighted that males had significantly higher $\delta^{15}\text{N}$ (coefficient estimate = 1.22, SE = 0.23, $t = 5.23$, $p < 0.001$) and $\delta^{13}\text{C}$ (coefficient estimate = 0.45, SE = 0.09, $t = 5.00$, $p < 0.001$); the tests on model residuals suggested that the assumptions of normality and homogeneity of variance between groups were met. The GEE analysis suggested that these differences remained significant even after accounting for any correlation within social groups ($\delta^{15}\text{N}$: $\chi^2 = 49.3$, $p < 0.001$; $\delta^{13}\text{C}$: $\chi^2 = 27.5$, $p < 0.001$).

The isotopic niche width of males had a 98% probability of being larger than that of females (ratio of the posterior modes = 3.1; Fig. 2). However, the probability of a sex difference in niche width dropped substantially when excluding the smaller male with female-like isotope values (mode ratio = 1.6; 79% probability of the niche width of males being larger than that of females; Fig. 2).

4. DISCUSSION

We detected clear differences in the $\delta^{15}\text{N}$ and, to a smaller extent, $\delta^{13}\text{C}$ values of male and female sperm whales sampled around the Balearic archipelago (Spain), where both sexes are observed to feed regularly in the summer months. Isotopic differences be-

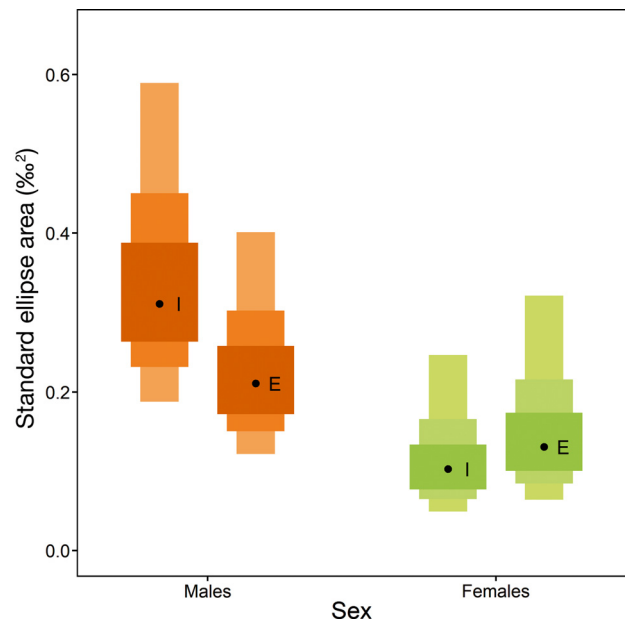

Fig. 2. Posterior distribution of standard ellipse areas (‰^2 , representing estimated niche widths) for males and females from the Bayesian model in SIBER, including (I) or excluding (E) the small male with female-like isotope values. Males show larger niche width, but this is somewhat dependent on the inclusion of the smaller sub-adult male. Black dots represent the posterior modes, while the shaded boxes indicate the 50, 75 and 95% credible intervals (darker to lighter colours)

tween the sexes in other ocean basins have been attributed to large-scale latitudinal segregation (Ruiz-Cooley et al. 2004, Borrell et al. 2013). Males in the Mediterranean cannot undergo such an extended latitudinal migration, but photo-identification evidence suggests they do move between the Balearics, the north-western basin and the Strait of Gibraltar (Drouot-Dulau & Gannier 2007, Carpinelli et al. 2014). Females could also move (Rendell et al. 2014), although social groups are believed to be more philopatric (Whitehead 2003). If individuals experience different isotopic baselines during movements within the western basin, this could be reflected in their isotopic values (Graham et al. 2010). However, given the short isotope turnover rates in odontocete skin (less than 1–1.5 mo; e.g. Browning et al. 2014, Giménez et al. 2016), the fact that samples were collected over a period of 4 mo and the within-sex consistency in our sample, stable isotope values are likely indicative of differences in the prey targeted by males and females when they are occurring around the Balearic archipelago. Despite the preliminary nature of our study, these results could therefore support the existence of marked, intraspecific

dietary differences in sperm whales belonging to this isolated, endangered population.

Higher $\delta^{15}\text{N}$ in males could indicate that they were feeding either on prey species at a higher trophic level, or on larger individuals of the same species (Hooker et al. 2001, Ruiz-Cooley et al. 2004, Newsome et al. 2010), in line with the limited available evidence from stomach content analysis in the Mediterranean (I. Foskolos pers. comm.) and other areas (Best 1999, Evans & Hindell 2004), and from stable isotopes in teeth (Mendes et al. 2007a, Borrell et al. 2013). The difference in $\delta^{13}\text{C}$ was small compared to the corresponding analytical precision ($0.23 \pm 0.15\text{‰}$). However, as supported by the results of the statistical analysis and the separate clustering of male and female samples along this axis (Fig. 1B), the variability within each group was smaller than that between groups, suggesting that differences in $\delta^{13}\text{C}$ could be ecologically relevant. If confirmed, this could indicate that the sexes were occupying habitats that differed at a fine scale, in accordance with visual and acoustic surveys in this and other low-latitude areas indicating that females are generally observed further offshore or in waters with distinct oceanographic characteristics (Best 1999, Gregr & Trites 2001, Pirodda et al. 2020).

A qualitative comparison with other published sperm whale isotopic values in the Mediterranean (Mazzariol et al. 2011, Praca et al. 2011, Pinzone et al. 2015) suggests some variation among studies (Fig. 3). Female sperm whales in our study also appear to have lower $\delta^{13}\text{C}$ than other Mediterranean deep-diving odontocetes, but comparable $\delta^{15}\text{N}$, whereas males are characterised by higher $\delta^{15}\text{N}$ than long-finned pilot whales *Globicephala melas* and lower $\delta^{13}\text{C}$ than Risso's dolphins *Grampus griseus* (Fig. 3) (Praca et al. 2011, Pinzone et al. 2015). Given the expected diet to skin discrimination factor in odontocetes (estimated to be approximately 1.5‰ for $\delta^{15}\text{N}$, and 1‰ for $\delta^{13}\text{C}$ in bottlenose dolphins *Tursiops truncatus*; Browning et al. 2014, Giménez et al. 2016) and reported values in putative prey samples (Praca et al. 2011, Fanelli et al. 2013, Navarro et al. 2013, Valls et al. 2017), our stable isotope results are broadly compatible with a diet of Histiotethidae (Fig. 3), as indicated by previous stable isotope (Praca et al. 2011) and stomach content analyses (Roberts 2003, Garibaldi & Podestà 2014, Foskolos et al. 2020). The comparison of a small number of stomachs from stranded males and females in the Eastern basin suggested that both sexes were mainly targeting the cephalopod *Histiotethis bonnellii*, but female diet was characterised by a higher proportion of the

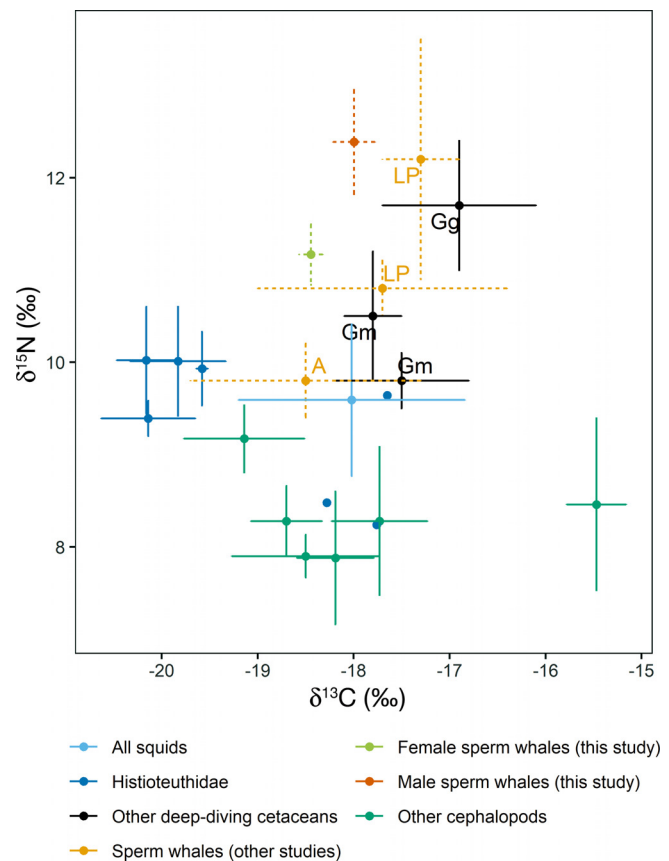

Fig. 3. Values of $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$ (mean and SD) in samples of Mediterranean sperm whales (dashed lines), other deep-diving odontocetes and putative prey (solid lines). Sperm whale samples include males and females from this study, individuals stranded along the Adriatic coast (A; Mazzariol et al. 2011) and individuals sampled in the Liguro-Provençal basin (LP; Praca et al. 2011, Pinzone et al. 2015). Other deep-diving odontocetes include long-finned pilot whales *Globicephala melas* (Gm) and Risso's dolphins *Grampus griseus* (Gg) (Praca et al. 2011, Pinzone et al. 2015). Putative prey include Histiotethidae (*Histiotethis reversa* and *H. bonnellii*; Praca et al. 2011, Fanelli et al. 2013, Valls et al. 2017), other cephalopods (other Teuthoidea, Octopoda, Sepioidea; Praca et al. 2011, Fanelli et al. 2013, Valls et al. 2017) and all squids (Navarro et al. 2013). Isotopic values in prey were not corrected by the discrimination factors

smaller congener *H. reversa*, which was also more prevalent in the diet of calves (I. Foskolos pers. comm.). These observations are in agreement with the isotopic differences between the sexes that we detected. However, uncertainty remains on the species or sizes targeted by male and female sperm whales in the Mediterranean and on the ecology of their prey. Further stomach content data and putative prey sampling are required to elucidate the diet of the 2 sexes in this region.

A series of mechanisms, either alone or in concert, could act to produce the observed sex differences in diet and the resulting fine-scale habitat segregation (Ruckstuhl 2007, Wearmouth & Sims 2008). Males, being larger, could have different energy requirements and diving abilities, which would allow them to target larger, deeper prey. Social affinities (that is, the tendency to associate with members of the same sex) are also possible in this highly social species (Whitehead 2003, Wearmouth & Sims 2008). Alternatively, social units might be responding to reproductive requirements, such as the need to care for young individuals with limited diving abilities, or to feed more intensely to cover the costs of gestation and lactation. As a result, females might also be more efficient at extracting resources, outcompeting males by scramble competition and forcing them to target different prey (Whitehead 2003, Breed et al. 2006). Sexual segregation would thus reduce intersexual competition when sexes occur in the same region, while allowing males to access the energy they need to sustain their size (Beck et al. 2007).

Determining whether observed differences are ancestral in the species or the result of adaptation in this isolated population would require further investigating dietary patterns outside the Mediterranean and a better understanding of the phylogenetic history of this population (Engelhaupt et al. 2009). It has been long recognised that male and female sperm whales from populations inhabiting other ocean basins are sexually segregated at a large, latitudinal scale (Whitehead 2003). The evidence from our study, combined with existing habitat modelling results (Pirootta et al. 2011, 2020), suggests that dietary differences occur even in this latitudinally restricted population and that the sexes could also segregate at a much smaller scale. Segregation between the sexes could act as a mechanism underpinning intraspecific resource partitioning in sperm whales, which is increasingly recognised as an important ecological and evolutionary process (e.g. Field et al. 2005, Svanbäck & Bolnick 2007).

Our results contribute to shed further light on the poorly understood ecology of the Mediterranean sperm whale population. Dietary differences may suggest that the broad sympatry between the sexes in the basin, possibly resulting from the latitudinal restrictions to male migration, could increase intraspecific competition for resources (Rendell & Frantzis 2016). Moreover, male and female feeding ecology might influence their movements at multiple scales (e.g. between and within portions of the Mediterranean, and over the seasons), which could help clarify

why social units are mostly encountered in specific areas, and specific habitats within those areas (Frantzis et al. 2014, Pace et al. 2018, Pirootta et al. 2020). Finally, understanding the ecology of this species will help explore some of the differences in social behaviour observed in the basin (e.g. the smaller size of social units compared to oceanic populations; Rendell & Frantzis 2016).

Dietary analysis should be repeated to expand the small sample size and investigate whether detected differences are consistent between seasons and years (Guerra et al. 2020). Comparison of male and female diving behaviour (particularly in terms of targeted depth layer) and feeding success would also contribute to further clarify the mechanisms underlying these sexual differences, although this analysis would have to account for any diurnal vertical migration of the prey. The GEE analysis suggested that any lack of independence among samples from the same group did not affect the significance of the effect of sex, but more samples could be used to assess group-specific dietary preferences (Marcoux et al. 2007). The sampling of several males in clusters, which were considered group encounters in the field, suggests that the social structure of this population, and the resulting isotopic differences, might vary significantly from those in other oceans, where considerable variation has already been documented (Whitehead et al. 2012). Further confirmatory sampling would also help quantify any geographic variation in diet within the sexes (for example, see potential differences among females sampled at different latitudes in Fig. 1) or within individuals (Guerra et al. 2020), as well as sex differences in niche width, possibly related to differences in size and metabolism, termed the forage selection hypothesis (Ruckstuhl 2007, Main 2008). Finally, we observed that one small (possibly younger) male showed similar isotopic values to females: this is consistent with the notion of ontogenetic shifts in sperm whale diet suggested by analysis of stable isotopes in teeth (Mendes et al. 2007b, Borrell et al. 2013), and with previous findings of similarities in the diet of females and immatures (e.g. Ruiz-Cooley et al. 2004), but again more independent samples are needed for confirmation.

Aside from fundamental insights into the ecology of this isolated population and the evolutionary forces that underpin the complex social structure of this species, understanding patterns of sexual segregation will be important for quantifying sex-specific rates of interactions with human activities (Wearmouth & Sims 2008). Collisions with vessels, entanglement in fishing gear and exposure to pollutants (including

noise) are some of the threats sperm whales face in the Mediterranean Sea (Rendell & Frantzis 2016). The differences in feeding ecology between males and females that we have highlighted here could reflect contrasting habitat use or diving behaviour, which, in turn, would imply a different susceptibility of the sexes to these threats. For example, different diving depths or frequency may affect the time spent near the surface, where individuals are vulnerable to vessel strikes (Laist et al. 2001). Moreover, the preferential use of certain habitats may modulate the amount of traffic, noise, fishing gear or plastic debris to which an individual is exposed (e.g. de Stephanis et al. 2013, Erbe et al. 2014, Cózar et al. 2015, Breen et al. 2016, Abrahms et al. 2019). Depending on the life history of a species, the demographic rates of one or both sexes may primarily influence population dynamics (Caswell 2001, Gerber & White 2014). Therefore, if sexual segregation were confirmed in Mediterranean sperm whales, the successful conservation of this Endangered population would require differential strategies targeting specific threats to either females or males in distinct areas.

Data availability. Data are available on the Open Science Framework repository (<https://osf.io/g7sxa/>)

Acknowledgements. This work was supported by the National Geographic Society (grant number EC-53116R-18). We are also grateful to WWF, the Swiss Cetacean Society and to all field volunteers. Thanks to Pilar Rubio, Pilar Teixidor and Asunción Borrell of the University of Barcelona and the Centres Científics i Tecnològics (CCiTUB) for their collaboration in stable isotope analysis. We thank Ilias Foskolos, Emer Rogan and Shane Gero for advice during the development of this study, and UCC for providing desk space to E.P. Data collection was carried out in compliance with Spanish regulations and under a permit to J.M.B. from the Directorate-General for Sustainability of the Coast and the Sea of the Ministry for the Ecological Transition. Finally, we thank Ilias Foskolos and 2 anonymous reviewers for their useful comments on the manuscript. This study was approved by the Animal Welfare and Ethics Committee (AWEC) of the University of St Andrews (UK).
